In a head-to-head, randomized, placebo-controlled study in 698 patients with moderate-to-severe claudication, Dawson and colleagues assigned patients to cilostazol (100 mg twice a day), pentoxifylline (400 mg 3 times a day), or placebo in an effort to improve maximal walking distance. After 24 weeks, the cilostazol group demonstrated a 54% mean increase in distance versus pentoxifylline, which demonstrated only a 30% mean increase (P <0.001). Similarly, a metaanalysis of 8 randomized, double-blind, placebo-controlled, parallel-design trials supported this conclusion with a reported increase in maximal walking distance and pain-free walking distance with cilostazol at doses of 50 mg and 100 mg twice-daily (P <0.05 for all) over placebo. Regrettably, improvement in walking distance has appeared to come with a price (in addition to the high drug cost); cilostazol has a “black box” warning from the FDA warning providers not to use this medication for patients with PAD and coexisting heart failure. However, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does suggest the use of this agent for patients with PAD who are not candidates for surgical interventions to improve severe IC that persists even after implementation of appropriate exercise therapy and therapeutic lifestyle changes.

**Pentoxifylline (Trental)**

Unlike cilostazol, pentoxifylline has produced results in clinical trials that are less promising, as illustrated by the randomized, placebo-controlled trial by Dawson and colleagues. Not only did cilostazol outperform pentoxifylline in improvement in walking distance, the improvement seen with pentoxifylline was no different from placebo (P = 0.82). This nonsignificant improvement in walking distance has been observed in other studies as well. Meanwhile, other metaanalyses of pentoxifylline in comparison with placebo for the improvement of maximal walking distance have shown some minimal improvement over placebo, but the average effects were relatively small. For these reasons, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does not recommend the use of this agent.

**EVALUATION OF THERAPEUTIC OUTCOMES**

It is vital that the patient be counseled on the evaluation measures that will be used to monitor the outcomes of therapeutic interventions for PAD. Various laboratory measurements will assess patient progress in glycemic control (e.g., hemoglobin A-1c) and lipid management (e.g., total cholesterol, LDL, HDL, and non-HDL cholesterol), while blood pressure checks in the clinic and patient home blood pressure monitoring can assess the effectiveness of antihypertensive therapy. Repeat exercise treadmill walking testing should be repeated at regular intervals (e.g., quarterly to biannually) to assess improvement or decline in walking duration and distance, as well as the time to pain onset while performing this activity. Repeat ABI measurements should be assessed at each patient visit to determine if there has been stabilization or progression of the disease process. Most importantly to many patients, simple concern and questioning about improvements to their daily quality of life will highlight your concern for their well-being and aid in an overall picture of the patient’s general state of health.

**INTERMITTENT CLAUDICATION (TABLE 29–2)**

**Cilostazol (Pletal)**

In a head-to-head, randomized, placebo-controlled study in 698 patients with moderate-to-severe claudication, Dawson and colleagues assigned patients to cilostazol (100 mg twice a day), pentoxifylline (400 mg 3 times a day), or placebo in an effort to improve maximal walking distance. After 24 weeks, the cilostazol group demonstrated a 54% mean increase in distance versus pentoxifylline, which demonstrated only a 30% mean increase (P <0.001).

**Pentoxifylline (Trental)**

Unlike cilostazol, pentoxifylline has produced results in clinical trials that are less promising, as illustrated by the randomized, placebo-controlled trial by Dawson and colleagues. Not only did cilostazol outperform pentoxifylline in improvement in walking distance, the improvement seen with pentoxifylline was no different from placebo (P = 0.82). This nonsignificant improvement in walking distance has been observed in other studies as well. Meanwhile, other metaanalyses of pentoxifylline in comparison with placebo for the improvement of maximal walking distance have shown some minimal improvement over placebo, but the average effects were relatively small. For these reasons, the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy does not recommend the use of this agent.

KEY CONCEPTS

1. Continuous hemodynamic monitoring with an arterial catheter or a central venous catheter capable of measuring mixed venous oxygen saturation (S\text{VO}_2) or central venous oxygen saturation (S\text{CVO}_2) should be used early and throughout the course of septic shock to assess intravascular fluid status and ventricular filling pressures, determine cardiac output (CO), and monitor arterial and venous oxygenation. They can be used for monitoring the response to drug therapy and guiding dosage titration.

2. Early goal-directed therapy with aggressive fluid resuscitation in the emergency department within the first 6 hours of presentation improves survival of patients with sepsis and septic shock.

3. Lactate production is increased under anaerobic conditions. Elevated serum lactate concentrations represent global perfusion abnormalities. Lactate may be used to assess repayment of oxygen to the tissues. Gastrointestinal tonometry and sublingual capnometry represent methods of assessing regional perfusion but are used infrequently.

4. Derangements in adrenergic receptor sensitivity or activity frequently result in resistance to catecholamine vasopressor and inotropic therapy in critically ill patients. These changes may be a function of endogenous catecholamine concentrations, dosage/duration of exposure to and type of exogenously administered vasopressors, stage of septic shock, preexisting illness, and other factors.

5. In refractory septic shock, rational use of vasopressor or inotropic agents should be guided by receptor activity, pharmacologic and pharmacokinetic characteristics, and regional and systemic hemodynamic effects of the drug and should be tailored to the patient's physiologic needs. Pharmacologically sound combinations of vasopressor and/or inotrope agents should be initiated early to optimize and facilitate rapid response.

6. Goals of therapy with vasopressors and inotropes should be predetermined and should optimize global and regional perfusion parameters (e.g., cardiac, renal, mesenteric, and periphery). This can be accomplished by continuous or intermittent measurements. Targeted goals should be central venous pressure (CVP) of 8–12 mm Hg (up to 15 mm Hg in mechanically ventilated patients, patients with preexisting left ventricular dysfunction, or patients with abdominal distension), mean arterial pressure (MAP) ≥65 mm Hg, and S\text{VO}_2/S\text{CVO}_2 ≥70%.

7. Dose titration and monitoring of vasopressor and inotropic therapy should be guided by the “best clinical response” while observing for and minimizing evidence of myocardial ischemia (e.g., tachydysrhythmias, electrocardiographic changes), renal (decreased glomerular filtration rate and/or urine production), splanchnic/gastric (low intramucosal pH, bowel ischemia), or peripheral (cold extremities) hypoperfusion, and worsening of partial pressure of arterial oxygen (P\text{aO}_2), pulmonary artery occlusive pressure, and other hemodynamic variables.

8. Much higher dosages of all vasopressors and inotropes than traditionally recommended are required to improve hemodynamic and oxygen-transport variables in patients with septic shock. Arbitrarily targeting vasopressor and inotropic therapy to supranormal values of global oxygen-transport variables cannot be recommended because of the lack of clear benefit and possible increased morbidity.

9. First-line therapy of septic shock is aggressive volume resuscitation with crystalloid or colloid types of fluids. Dopamine or norepinephrine typically is used as the initial vasopressor agent for hemodynamic support. Dopamine is limited by its ability to increase CO and complications of tachycardia, tachydysrhythmias, increase in pulmonary artery occlusive pressure, and decrease in splanchnic oxygen use. Low-dose dopamine should not be used to prevent renal failure. Norepinephrine may achieve greater hemodynamic response than dopamine and is less likely to cause tachydysrhythmias and a decrease in splanchnic oxygen utilization.

10. Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmia associated with the use of other agents. Its effects on cardiac performance and splanchnic oxygen utilization are variable.

11. Epinephrine appears to be effective as a single agent and as an add-on agent. It is particularly useful in the young, in patients with otherwise healthy myocardium, and potentially in patients when used early in the course of treatment. However, because epinephrine causes a significant increase in lactate and worsening of splanchnic oxygen utilization, it is not the agent of first choice in patients with septic shock. It should be used cautiously in patients with a history of coronary artery disease or underlying cardiac disturbances.

12. Dobutamine may be used as adjunctive therapy for its inotropic effect. It enhances CO and may increase S\text{VO}_2/S\text{CVO}_2. Concurrent vasopressor therapy is needed because dobutamine causes vasodilation. Dobutamine therapy may be limited by tachycardia and dysrhythmias.
Shock is an acute, generalized state of inadequate perfusion of critical organs that can produce serious pathophysiologic consequences, including death, when therapy is not optimal. Shock is defined as systolic blood pressure <90 mm Hg or reduction of at least 40 mm Hg from baseline with perfusion abnormalities despite adequate fluid resuscitation.1 Previously, mortality from septic or cardiogenic shock exceeded 70% but now ranges between 30% to 50%.2–5 This chapter reviews the theory and current status of hemodynamic monitoring and presents an update on the optimal use of inotropes and vasopressor drugs in shock states, specifically septic shock.6–19

Hemodynamic and perfusion monitoring can be categorized into two broad areas: global and regional monitoring. Global parameters, such as systemic blood pressure and pulse oximetry, assess perfusion and oxygen utilization of the entire body. Regional monitoring techniques, such as tonometry, focus on oxygen delivery and subsequent changes in metabolism of individual organs and tissues. Normal values for commonly monitored parameters are listed in Table 30–1. Evidence-based goals of therapy are listed in Table 30–2.6–19 The adequacy of regional perfusion can be assessed by monitoring techniques such as arterial catheterization, measuring arterial blood gases, and measuring oxyhemoglobin saturation with pulse oximetry, but these methods are not commonly available outside the ICU.

### Table 30-2: Evidence-Based Treatment Recommendations for Management of Severe Sepsis or Septic Shock

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Grade</th>
</tr>
</thead>
<tbody>
<tr>
<td>In patients requiring vasopressors, an arterial catheter should be placed as soon as practical to monitor blood pressure. Begin resuscitation immediately in patients with hypotension or elevated serum lactate.</td>
<td>1D</td>
</tr>
<tr>
<td>Goals of resuscitation should include (1) CVP 8–12 mm Hg; (2) MAP ≥65 mm Hg; (3) urine production ≥0.5 mL/kg/h; and (4) SaO₂ or Svo₂ ≥70%.</td>
<td>1C</td>
</tr>
<tr>
<td>If Svo₂ or Svo₂ ≥70% not achieved, consider the following: (1) further fluid administration, (2) transfuse packed red blood cells to hematocrit ≥30%; or (5) dopamine infusion ≤20 mcg/kg/min. Fluid resuscitate using crystalloids or colloids. Use a fluid challenge technique to determine associated hemodynamic improvement. Administer 1000 mL of crystalloid or 300–500 mL of colloid over 30 minutes. More rapid and larger volumes may be required. Rate of fluid administration should be reduced if cardiac filling pressures increase without concurrent improvement. Use vasopressors to maintain MAP ≥65 mm Hg. Either dopamine or norepinephrine centrally administered are the initial vasopressors of choice.</td>
<td>1B</td>
</tr>
<tr>
<td>Epinephrine, phenylephrine, or vasopressin should not be administered as the initial vasopressor. Vasopressin 0.03 units/min may be subsequently added to norepinephrine with an anticipation of an effect equivalent to norepinephrine alone. Use epinephrine as the first alternative agent when blood pressure is poorly responsive to dopamine or norepinephrine. Do not use low-dose dopamine for renal protection. Use dobutamine in patients with myocardial dysfunction as supported by elevated cardiac filling pressures and low CO. Do not increase cardiac output to predetermined abnormal indices. Consider intravenous hydrocortisone when hypotension remains poorly responsive to adequate fluid resuscitation and vasopressors. ACTH stimulation test is not recommended to identify the subset of patients who should receive hydrocortisone. Hydrocortisone is the preferred corticosteroid. Hydrocortisone dose should be ≤300 mg/day. Corticosteroid therapy may be weaned once vasopressors are no longer required. Do not use corticosteroids to treat sepsis in the absence of shock unless the patient’s endocrine or corticosteroid history warrants it.</td>
<td>2B</td>
</tr>

| A higher target CVP of 12–15 mm Hg may be required in the presence of mechanical ventilation or preexisting left ventricular dysfunction or abdominal distension. ACTH, adrenocorticotropic hormone; CO, cardiac output; CVP, central venous pressure; DO₂, oxygen delivery; MAP, mean arterial pressure; Svo₂, central venous oxygen saturation; SaO₂, mixed venous oxygen saturation. Level of recommendations: 1, strong recommendation indicating that the intervention’s desirable effects clearly outweigh its undesirable effects; 2, weak recommendation indicating that the tradeoff between desirable and undesirable effects is less clear. Quality of evidence: A, supported by a randomized control trial; B, supported by a downgraded randomized control trial or upgraded observational studies; C, supported by observational studies; D, supported by case series or expert opinion. Based on data from references 6–19.
by indices of specific organ perfusion. These measurements include coagulation abnormalities (disseminated intravascular coagulation), altered renal function with reduced urine production or increased serum concentrations of blood urea nitrogen and creatinine, altered hepatic parenchymal function with increased serum concentrations of transaminases and bilirubin, altered gastrointestinal perfusion manifested by ileus and diminished bowel sounds, cardiac ischemia with elevated troponin levels and electrocardiographic changes, and altered sensorium. Although none of these indices alone is a reliable indicator of adequate resuscitation, they offer immediate detection and may be prognostic of recovery when combined and defined at the level of organ function. As a result, these indices are frequently used as surrogate endpoints for the goals of resuscitation. While it is assumed that normalization of these parameters infers benefit, the clinician must first treat the patient rather than relying solely on data from continuous monitoring to guide therapy.

GLOBAL PERFUSION MONITORING

ARTERIAL BLOOD PRESSURE MEASUREMENT

Mean arterial blood pressure (MAP) is the product of cardiac output (CO) and systemic vascular resistance (SVR). Conditions that may lower blood pressure in critically ill patients include cardiac failure (etiologies may be myocardial infarction, arrhythmia, acute heart failure, or valvular disease) and hypovolemia (etiologies may be hemorrhage, intractable diarrhea, or heat stroke) by lowering CO and vasodilation (etiologies may be sepsis, drugs, anaphylaxis, acute hepatic failure, or neurotrauma) by lowering SVR. Arterial blood pressure is the end point of therapy; however, restoration of adequate perfusion pressure is the primary criterion of effectiveness of resuscitation. Profound hypotension (MAP <50 mm Hg) is associated with a pressure-dependent decrease in coronary and cerebral blood flow and may rapidly produce myocardial and cerebral ischemia. Arterial blood pressure can be determined by noninvasive and invasive methods. All noninvasive blood pressure monitoring techniques depend on the use of an occluding cuff. Systolic and diastolic blood pressures are further determined by auscultation, palpation (systolic pressure only), oscillometry, or Doppler technique (systolic pressures are most reliable). Auscultation is the most commonly used method outside the intensive care unit (ICU). Its use, however, is limited in patients with hypovolemia, hypothermia, or cardiogenic shock when pulses or Korotkoff sounds may be difficult to hear. Similar constraints exist for the palpation and oscillometric methods. However, oscillometry is preferred in edematous patients. Oscillometry measures blood pressure by sensing arterial blood pressure changes, or oscillations, against an inflated cuff. Rapid changes in oscillation amplitude correspond to systolic and diastolic pressure. It is the only noninvasive method to measure MAP even in low-flow states and lends itself to automatic cycling and serial measurements (every 1–3 minutes) that do not require operator intervention, a key component in ICU monitoring. The use of narrow cuffs or cuffs applied too loosely can result in falsely high readings, whereas wide cuffs may produce falsely low readings. Fingertip devices offer another avenue for continuous indirect blood pressure measurement, but their accuracy in ICU patients may be significantly diminished by concurrent administration of vasoactive drugs.

The use of invasive arterial catheters makes possible the continuous measurement of MAP as well as procurement of blood samples for blood gas monitoring. The radial artery is the most commonly used vessel, but the dorsalis pedis, femoral, brachial, and axillary arteries and the umbilical artery in the newborn also can be accessed. This method of blood pressure monitoring is the standard technique used in the ICU against which all other methods are compared. Major complications of peripheral artery catheterization include infection and distal ischemia. Acute distal ischemia and catheter-associated bacteremia occur in <1% of catheter insertions. This translates to 2.9% of bloodstream infections per 1,000 catheter-days. Ischemia is most common in patients with multiple or prolonged arterial cannulations, hypertension, or vasopressor therapy. Invasive techniques are labor intensive, require aseptic techniques, and offer potential sources of equipment errors, such as length and quality of tubing, air bubbles, stopcocks, thrombus formation, tube kinking, and transducer placement. Hypertension, advanced age, and atherosclerosis also may affect the accuracy of invasive blood pressure readings.

CENTRAL VENOUS CATHETER

The central venous catheter is used to measure the central venous pressure (CVP), to obtain venous blood gas samples, and to administer drugs or fluids directly to the central circulation. A triple-lumen catheter frequently is used, whereby drugs with known incompatibility can be administered. Blood volume, venous wall compliance, right-sided cardiac function, intraabdominal and intrathoracic pressures, and vasopressor therapy affect CVP. The CVP is not a reliable estimate of blood volume but can be used to qualitatively assess blood volume changes in patients during the early phases of fluid resuscitation. The goal of fluid administration is to maintain the CVP at 8 to 12 mm Hg, but values of 15 mm Hg may be targeted in mechanically ventilated patients or patients with abdominal distension or preexisting ventricular dysfunction. Sustained elevated pressures may be indicative of fluid overloading. Few data support the use of continuous CVP monitoring in the ICU. However, CVP monitoring of fluid therapy during resuscitation of septic shock is associated with reduced mortality.

PULMONARY ARTERY CATHETER

Pulmonary artery catheterization provides multiple cardiovascular parameters, including CVP, pulmonary artery pressure, pulmonary artery occlusive pressures (PAOP), CO, SVR, and the mixed-venous oxygen saturation (SvO₂). Ideally, the pulmonary artery catheter should be positioned fluoroscopically; however, satisfactory placement also may be obtained by observing pulmonary artery pressure readings and electrocardiographic waveforms during catheter advancement. Proper positioning in the lower lung (zone 3) is essential to measure PAOP and to prevent distal pulmonary artery collapse. Inflation of the balloon at the catheter tip occludes the pulmonary artery, isolates the distal catheter tip from the right side of the heart, and allows the user to measure the PAOP, an approximate measure of the left ventricular end-diastolic volume and a major determinant of left ventricular preload. Poor wedging may be caused by catheter migration, patient movement, mechanical ventilation, or eccentric balloon inflation. Pulmonary artery catheters equipped with a distal thermostor also allow measurement of CO by thermodilution. Rapid injection of saline or dextrose solutions via the right atrial port allows complete mixing of blood with the injectate, and the resulting change in blood temperature is measured in the pulmonary artery. From the temperature change, the patient’s CO can be calculated. Newer pulmonary artery catheters contain a temperature coil that intermittently warms the blood in the right ventricle for near-continuous CO measurement. Significant tricuspid regurgitation, an intracardiac shunt, and significant positive end-expiratory pressure decrease the validity of CO measurements. The most common complications of pulmonary artery catheterization include mural thrombus formation (14%–91%), transient ventricular tachydysrhythmias (11%–63%), pulmonary infarction (1%–7%), pulmonary artery rupture (0.06%–2.0%), and sepsis (0.3%–0.5%).
Most pulmonary artery catheters are heparin bonded, and the relative risk (RR) of infection is 2.6 per 1,000 patient-days, similar to the risk with central venous catheters of 2.3 per 1,000 patient-days. Controversy surrounds the utility and safety of the pulmonary artery catheter, including issues surrounding correct placement and impact of the device on patient outcome. Recent studies failed to demonstrate beneficial outcomes with the use of the pulmonary artery catheter. The most recent guidelines suggest careful evaluation of the indications and the risk of placing a pulmonary artery catheter for resuscitation of critically ill patients.

The optimal PAOP needs to be individualized for each patient. Administering a fluid bolus followed by simultaneous PAOP and CO measurements with the goal of increasing the PAOP until CO does not change can be accomplished and is based on Starling’s law of the heart. However, clinical experience suggests that most patients have an optimal response to PAOP values in the range from 12 to 15 mm Hg.

**Clinical Controversy: CVP vs PAOP**

Limited data are available comparing the use of CVP and PAOP for guiding therapy in patients with shock. The results of recent studies of critically ill patients suggest CVP and PAOP are equivalent in terms of clinical outcomes, including mortality. Therefore, a pulmonary artery catheter should be inserted when hemodynamic data are needed that cannot be obtained from a central venous catheter or when the validity of measurements from the central venous catheter is questionable.

Other methods used to assess CO include carbon dioxide (CO₂) partial rebreathing and esophageal Doppler. The CO₂ partial rebreathing technique compares end-tidal CO₂ partial pressure obtained during a nonrebreathing period with that obtained during a subsequent rebreathing period. The ratio of change in end-tidal CO₂ and CO₂ elimination estimates CO but must be corrected for blood shunting. Poor to acceptable agreement exists between this method and the thermodilution method of assessing CO in critically ill patients. Also, low minute ventilation, a high shunt fraction, or a high cardiac output produce inaccurate results. The esophageal Doppler technique measures flow velocity in the descending aorta by means of a Doppler transducer. CO is calculated based on the diameter of the aorta, the distribution of CO to the aorta, and the flow velocity of blood in the aorta. The CO reported by this method correlates with therapeutic interventions and demonstrates excellent agreement with the pulmonary artery catheter. Unfortunately, this method is technologically difficult and may not produce reliable measurements over time.

**Oxygen Delivery and Consumption**

Tissue oxygen debt is indicative of organ damage in critical illness. In normal individuals, oxygen consumption (VO₂ or VO₂L, indexed to body surface area) depends on DO₂ (or DO₂L) up to a certain critical level (VO₂ flow dependency). At this point, tissue oxygen requirements apparently are satisfied, and further increases in DO₂ will not alter VO₂ (VO₂ flow independency). Although animal models of sepsis substantiate this relationship, studies in critically ill humans show a continuous, pathologic dependence relationship of VO₂ with DO₂. The VO₂/DO₂ ratio, or oxygen extraction ratio (O₂ ER), can be used to assess adequacy of perfusion and metabolic response. Maintaining the oxygen extraction ratio (O₂ ER) at <25% without a changing VO₂ may be helpful in maintaining or improving the body’s reserve in meeting the oxygen demands.

However, low VO₂ and O₂ ER values are indicative of poor oxygen utilization and lead to greater mortality. Patients who are able to increase VO₂ when DO₂ is increased show improved survival. This finding became the basis for targeting supranormal DO₂ and VO₂ values in the treatment of ICU patients. However, a meta-analysis of randomized clinical trials involving 1,016 adult ICU patients failed to show that achievement of this goal improved mortality. This may have been due in part to the heterogeneous nature of the ICU patients studied and therapies provided, lack of study blinding, crossover patients (control patients who achieve supranormal DO₂ and VO₂ values by themselves), or lack of adequate control of cointerventions. The debate continues in more homogeneous patient populations. For example, in high-risk surgical patients, supranormal DO₂ values decrease mortality except in the subgroup of patients exceeding 75 years of age in whom achieving DO₂L >600 mL/m²/min show mixed mortality results.

A review of alternative potential mechanisms of beneficial effect of supranormal DO₂ suggests that catecholamines exert antiinflammatory actions by modulating cytokine response. In general, catecholamines inhibit the production of inflammatory cytokines (e.g., interleukin [IL]-6, tumor necrosis factor [TNF]-α) and may enhance synthesis of antiinflammatory cytokine (e.g., IL-4 and IL-10). The actions of epinephrine on these cytokines are blocked by propranolol and thus are mediated by adrenergic β-receptors.
Another problem with therapy directed to achieve supranormal oxygen transport values is that the apparent linear relationship between \( \text{DO}_2 \) and \( \text{VO}_2 \) has been questioned because both share variables, and this mathematical coupling can produce artifactual relationships between variables.\(^{17-21} \) The \( \text{DO}_2 \) and \( \text{VO}_2 \) indexed parameters are calculated as follows:

\[
\text{DO}_2 = \text{CI} \times \text{CaO}_2 \\
\text{VO}_2 = \text{CI} \times (\text{CaO}_2 - \text{CVO}_2),
\]

where \( \text{CI} \) = cardiac index, \( \text{CaO}_2 \) = arterial oxygen content determined by hemoglobin concentration and \( \text{Sao}_2 \), and \( \text{CVO}_2 \) = mixed venous oxygen content determined by hemoglobin concentration and \( \text{Svo}_2 \).

However, variable relationships between \( \text{DO}_2 \) and \( \text{VO}_2 \) are observed when \( \text{VO}_2 \) is measured independently by indirect calorimetry. Therefore, a linear relationship between \( \text{DO}_2 \) and \( \text{VO}_2 \) may be the result of mathematical coupling or flow-dependent \( \text{VO}_2 \). Currently available data do not support the concept that patient outcome or survival is improved by treatment measures directed toward achieving supranormal \( \text{DO}_2 \) and \( \text{VO}_2 \) values.\(^{10} \) In fact, a consensus conference concluded that although pulmonary artery catheterization is useful for guiding therapy, routinely increasing cardiac index to predetermined supranormal values does not improve outcome.\(^ {32} \) Furthermore, achievement of a supranormal \( \text{DO}_2 \) does not ensure parallel improvements in regional organ blood flow and oxygenation. One approach that may decrease the effect of mathematical coupling and provide individualized therapy may lie in titrated therapy, with sequential measurements of \( \text{DO}_2 \) and \( \text{VO}_2 \) to achieve \( \text{VO}_2 \) flow independence along with normalization of blood lactate and hemodynamic parameters.

The most recent data regarding goal-directed therapy in the hemodynamic support of sepsis relates to the importance of achieving predetermined parameters early in the management of sepsis.\(^ {14} \) In a meta-analysis of early (defined as 8–12 hours postoperatively or before the development of organ failure) versus late (defined as after the onset of organ failure) resuscitative efforts in patients stratified according to severity of illness (determined by control group mortality >20% [12 studies] or <15% [9 studies]) and targeting supranormal oxygen-transport variables, the data suggest that timing of resuscitation matters.\(^ {15} \) Early goal-directed therapy reduced mortality and the development of organ failure in patients who were more severely ill and when therapeutic interventions produced differences in \( \text{DO}_2 \). Moreover, outcome was not improved significantly in less severely ill patients (control group mortality <15% and normal \( \text{DO}_2 \) values as goals) or when therapy did not improve \( \text{DO}_2 \).

More important than achieving supranormal \( \text{DO}_2 \) is the rapid initiation of therapy. In a prospective, randomized controlled trial, Rivers et al. demonstrated a significant reduction in mortality (30.5% vs 46.5%; \( P < 0.001 \)) in patients with severe sepsis and septic shock randomized to receive therapy based on goal-directed hemodynamic end points that were achieved within 6 hours of hospital presentation.\(^ {10} \) They used a strategy of serial administering (1) fluids rapidly to achieve CVP 8–12 mm Hg, (2) vasopressor agents to achieve MAP at least 65 mm Hg, (3) red blood cell transfusion to maintain hematocrit ≥30%, and (4) dobutamine to achieve \( \text{ScVO}_2 \) ≥70%. This approach demonstrates the benefits of initiating therapy early in the course of sepsis and directs therapy toward clearly defined goals in a consistent manner. The results of several evaluations of protocols or order sets designed to achieve the hemodynamic end points of early goal-directed therapy show that implementation is easily accomplished, cost is reduced, and patient outcomes, including survival, are improved.\(^ {26-41} \) A recent meta-analysis of nine studies showed reduced mortality when quantitative resuscitation goals are used to guide therapy (odds ratio [OR] 0.64; 95% confidence interval [CI] 0.43–0.96; \( P = 0.03 \)).\(^ {42} \) Therefore, healthcare facilities should implement strategies to achieve early goal-directed therapy using the predefined hemodynamic variables of the study by Rivers et al.\(^ {10} \)

### BLOOD LACTATE

Lactate is a metabolic product of pyruvate. Its production is increased under anaerobic conditions, such as may occur during shock. Blood lactate concentrations are used as a diagnostic and prognostic tool in sepsis; they also are used to measure the repayment of oxygen debt to tissues.\(^ {17-21,34} \) It is a useful tool in combination with \( \text{DO}_2 \) and \( \text{VO}_2 \) because these measures change independently of one another. Serial lactate concentrations may show better correlation with outcome than oxygen transport parameters and may be superior to hemodynamic markers in determining adequacy of restoration of systemic oxygenation.\(^ {17-21,34} \) However, several caveats guide the use of lactate concentrations in septic patients. First, lactate may accumulate in patients with other conditions, such as significant hepatic dysfunction or acute respiratory distress syndrome, who are not in shock. Second, both well-perfused and poorly perfused tissues contribute to arterial and mixed venous lactate concentrations and therefore are not reflective of regional perfusion. Third, although increased lactate concentrations have been correlated with increased mortality, the utility of blood lactate measurements in guiding therapy has not been clearly demonstrated. Fourth, elevated lactate concentrations may result from cellular metabolic failure rather than global hypoperfusion in shock. Serial blood lactate measurements are more useful than single isolated measurements and continuously elevated concentrations are predictive of morbidity and mortality.

### REGIONAL PERFUSION MONITORING

#### GASTROINTESTINAL TONOMETRY

Blood pressures, \( \text{CO} \), blood lactate, and global oxygen homeostasis parameters do not offer information about the function of individual organs. Organ-specific hypoxia may be evident by coagulopathy as indicated by thrombocytopenia (platelet count <100,000/L and/or prolonged clotting times [international normalized ratio >1.5 or activated partial thromboplastin time at least 1.5-fold the upper limit of normal]), impaired renal function with urine production <0.5 mL/kg/h and/or increased serum concentrations of blood urea nitrogen and creatinine, altered hepatic function with substantially increased serum concentrations of transaminases and bilirubin, altered gastrointestinal perfusion manifested by ileus and diminished bowel sounds, cardiac ischemia with elevated troponin levels and electrocardiogram changes, and altered sensorium.\(^ {7,22} \) Objective measurement of regional perfusion to detect inadequate tissue oxygenation has focused on the mesenteric/splanchnic circulation, which is sensitive to changes in blood flow and oxygenation for

---

**CLINICAL CONTROVERSY: GOALS OF EARLY GOAL-DIRECTED THERAPY**

The results of studies cannot delineate which end point or combination of end points was most beneficial with respect to early goal-directed therapy. These studies also offer limited information about specific interventions to achieve the predefined goals. In addition, whether these goals must be maintained after resuscitation is unknown. Several studies are ongoing to address some of these issues.
Cardiovascular Disorders

SECTION 2

Cardiovascular Disorders

Tonometry, in general, inconsistently predicts mortality. Gastric tonometry remains uncertain because mucosal $P_{\text{CO}_2}$ is influenced by arterial $P_{\text{CO}_2}$, the mucosal–arterial $P_{\text{CO}_2}$ difference ($P_{\text{CO}_2}$ gap) likely is the optimal measurement.

Gastric tonometry can be performed using either a saline- or air-filled balloon. The time delay (30 minutes) associated with equilibration of saline inside the balloon makes this method impractical for monitoring of resuscitation and inconvenient for routine bedside monitoring. An air-filled balloon requires a shorter equilibrium time, is simpler to use, and is equally accurate. However, the clinical utility of gastric tonometry remains uncertain. Clinical trials of pH-directed therapy do not show that it aids resuscitation when other goals are concomitantly targeted. Gastric tonometry, in general, inconsistently predicts mortality.

Evidence suggests that the most proximal part of the gastrointestinal tract, the sublingual mucosa, may be an acceptable location for monitoring regional perfusion and $P_{\text{CO}_2}$. Unlike gastrointestinal circulation, limited intra- and interpatient variability exists in the microvasculature and only few arterioles are available for assessment. Sublingual capnometry is noninvasive, is not technically complex, and provides results within minutes. The device consists of a disposable sublingual carbon dioxide pressure ($P_{\text{sl CO}_2}$) sensor, a fiberoptic cable that connects the disposable sensor to a blood gas analyzer, and a blood gas monitoring instrument. Small studies of critically ill patients with and without sepsis and septic shock show that the $P_{\text{sl CO}_2}$ and the sublingual-to-arterial $P_{\text{CO}_2}$ gap correlate better with the enhancement of DO$_2$ with dobutamine than the mucosal $P_{\text{CO}_2}$ and the mucosal-to-arterial $P_{\text{CO}_2}$ gap. The initial sublingual-to-arterial $P_{\text{CO}_2}$ gap is a better predictor of mortality. These pilot studies must be expanded before this technology becomes part of routine practice, but it offers the possibility of noninvasive measurement of regional perfusion. Of note, some institutions have incorporated the $P_{\text{sl CO}_2}$ into their algorithms of early goal-directed therapy in an effort to provide additional information about the effectiveness of therapies during resuscitation.

MYOCARDIAL DYSFUNCTION

Although loss of vascular tone is the hallmark of septic shock, myocardial dysfunction characterized by transient impairment of contractility is a recognized complication. The range of left ventricular ejection fraction (LVEF) upon presentation is wide, but approximately 35% of patients with septic shock have low ventricular hypokinesis (mean ejection fraction 38% ± 17%) and low CO. Because LVEF also is affected by preload and afterload, the low SVR of septic shock may mask depressed myocardial contractility that may be revealed upon restoration of MAP by administration of fluid and vasopressors. Therefore, CO may not reflect the extent of myocardial dysfunction. While it requires technical and interpretive training, echocardiography is a relatively simple method of assessing cardiac function. It can assess chamber size, ventricular contractility, valve function, and blood flow. Patients with tissue hypoxia or a hyper-contractile left ventricle may benefit from fluid administration or vasopressor therapy; whereas, patients with poor left ventricular function may require inotropic intervention. Like sublingual capnometry, some institutions use echocardiography to direct resuscitation therapies.

Cardiac troponin release in septic patients occurs in the absence of flow-limiting disease, likely due to a loss in membrane integrity with subsequent leakage or microvascular thrombosis. Elevation of cardiac troponin concentrations in patients with sepsis indicates left ventricular dysfunction and portends a poor prognosis. Troponin concentrations also correlate with the duration of hypotension and the intensity of vasopressor therapy. Early recognition of myocardial dysfunction is crucial for administration of appropriate therapy. In the absence of other mechanisms for assessing cardiac function, echocardiographic findings and troponin concentrations may help guide and monitor therapy. Whereas cardiac troponins may be integrated into the monitoring of myocardial dysfunction to identify patients requiring aggressive therapy, natriuretic peptides show variable correlation with LVEF and should not be routinely monitored.

VASOPRESSORS AND INOTROPES

Vasopressors and inotropes in patients with septic shock are required when volume resuscitation fails to maintain adequate blood pressure (MAP ≥ 65 mm Hg) and organs and tissues remain hypoperfused despite optimizing CVP to 8 to 12 mm Hg or PAOP to 12 to 15 mm Hg. However, vasopressors may be needed temporarily to treat life-threatening hypotension when filling pressures are inadequate despite aggressive fluid resuscitation. Inotropes are frequently used to optimize cardiac function in cases of cardiogenic shock. The clinician must decide on the choice of agent, therapeutic end points, and safe and effective doses of vasopressors and inotropes to be used. This section reviews adrenergic receptor pharmacology, exogenous catecholamine use, and alterations in receptor function in critically ill patients. It also provides guidelines for the clinical use of adrenergic agents, optimization of pharmacotherapeutic outcomes, and minimization of adverse effects in critically ill patients with septic shock. Therapies of hypovolemic shock and cardiogenic shock are discussed in other chapters.

Of note, agents other than catecholamines have been used as inotropes and vasopressors in shock states. They include phosphodiesterase III inhibitors, naloxone, nitric oxide (NO) synthase (NOS) inhibitors, and calcium sensitizers. This chapter focuses on catecholamines. Vasopressin and corticosteroids, as they relate to septic shock, also are emphasized because they have pharmacologic interactions with catecholamines, possess hemodynamic effects, and are frequently used.

CATECHOLAMINE RECEPTOR PHARMACOLOGY

Comparative receptor activities of endogenous and exogenously administered catecholamines is summarized in Table 30–3. Endogenous catecholamines are responsible for regulation of

D, dopamine; NO, nitric oxide; V, vasopressin.
Based on data from references 6–15, 49–53.

Vascular and bronchiolar smooth muscle tone and myocardial contractility. These effects are mediated by sympathetic adrenergic receptors of the autonomic nervous system located in the vasculature, myocardium, and bronchioles. Postsynaptic adrenoceptors are located at or near the synaptic junction. These receptors can be activated by naturally circulating or exogenous catecholamines (e.g., norepinephrine, epinephrine, and phenylephrine), whereas presynaptic adrenoceptors are stimulated by locally released neurotransmitters (e.g., norepinephrine) and are controlled by a negative feedback mechanism.

The signal transduction pathways associated with catecholamine and vasopressin-induced effects in the heart and blood vessels are illustrated in Figure 30–1. 6, 18–49, 51–53 Agonists of β-adrenoceptors and dopamine (D₂) receptors stimulate adenylate cyclase by a G-protein (G₁)–dependent mechanism (Fig. 30–1, top). Adenylate cyclase generates cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP), cAMP-dependent protein kinase A, which is activated by elevations in intracellular cAMP, phosphorylates target proteins to modify cellular function. Through these mechanisms, β₁-adrenoceptor activation exerts positive inotropic and chronotropic effects in the heart, and β₂-adrenoceptor and D₁-receptor activation induces vascular smooth muscle relaxation. Agonists of α₁-adrenoceptors stimulate phospholipase C (PLC) through a G-protein (G₁)–dependent process (Fig. 30–1, bottom). PLC-β produces inositol triphosphate and diacylglycerol from cell membrane phosphatidylinositol bisphosphate. Diacylglycerol activates protein kinase C, an enzyme that phosphorylates several key proteins (e.g., extracellular signal–regulated kinases, c-Jun NH2-terminal kinases, and mitogen-activated protein kinases) that modify cellular function (e.g., hypertrophy). Inositol triphosphate elicits the release of calcium from intracellular stores, such as the sarcoplasmic reticulum. Calcium forms a complex with calmodulin, which then activates calcium–calmodulin-dependent protein kinases (CaMK). CaMKs phosphorylate target proteins to alter cellular function. Myosin light-chain kinase is an example of a CaMK. Its action of phosphorylating myosin light chain leads to vascular smooth muscle contraction.

The normal heart contains primarily postsynaptic β₁-receptors, which when stimulated cause increased rate and force of contraction. This effect is mediated by activation of adenylate cyclase and subsequent generation and accumulation of cAMP. Stimulation of postsynaptic cardiac α₁-receptors causes a significant increase in contractility without an increase in rate, an effect mediated by PLC rather than adenylate cyclase. The increased contractility is more pronounced at lower heart rates and has a slower onset and longer duration in comparison with β₁-mediated inotropic response. Presynaptic α₁-adrenoceptors also are found in the heart and appear to be activated by norepinephrine released by the sympathetic nerve itself. Their activation inhibits further norepinephrine release from the nerve terminal.

Both presynaptic and postsynaptic adrenoceptors are present in the vasculature. Postsynaptic α₁- and α₂-receptors mediate vasoconstriction, whereas postsynaptic β₁-receptors induce vasodilation. Presynaptic α₁-receptors inhibit norepinephrine release in the vasculature, also promoting vasodilation. Presynaptic β₁-receptors promote neurotransmitter release. Stimulation of peripheral D₁-receptors produces renal, coronary, and mesenteric vasodilation and a natriuretic response. Stimulation of D₂-receptors inhibits norepinephrine release from sympathetic nerve endings, sequesters prolactin and aldosterone, and may induce nausea and vomiting. D₁- and D₂-receptor stimulation also suppresses peristalsis and may precipitate ileus.

Vasopressin-induced vasoconstriction occurs through a variety of direct and indirect mechanisms. 51–53 Stimulation of vascular vasopressin (V), receptors causes vasoconstriction by receptor-coupled activation of PLC and calcium release from intracellular stores via secondary messengers similar to α₁-adrenergic stimulation (Fig. 30–1, bottom). Vasopressin also directly inhibits vascular potassium-sensitive ATP channels to produce vasoconstriction (Fig. 30–1, bottom). V₁-receptor stimulation inhibits the actions of IL-1β and thereby facilitates vasoconstriction. Vasopressin also increases the activity of adrenergic receptors. The greatest vasoconstriction occurs in the skin and soft tissue, skeletal muscle, fat tissue, pancreas, and thyroid gland. In contrast, vasopressin causes vasodilation in the cerebral, pulmonary, coronary, and selected renal vascular beds by enhancing endothelial NO release through V₁-receptor stimulation in these tissues. 51–53 Vasopressin has minimal to no inotropic or chronotropic effects.
V$_2$ receptors located in the kidneys are responsible for the antidiuretic properties of vasopressin. Stimulation of V$_2$ receptors facilitates integration of aquaporins into the luminal cell membrane of distal tubules and collecting duct capillaries to increase permeability and thus retain intravascular volume. However, vasopressin stimulation of V$_1$ receptors causes vasoconstriction of efferent arterioles and relative vasodilation of afferent arterioles to increase glomerular perfusion pressure and filtration rate to enhance urine production.

Vasopressin rapidly increases serum cortisol concentration by stimulating V$_3$ receptors in the pituitary gland to enhance the release of adrenocorticotropic hormone (ACTH). Cortisol helps regulate the proinflammatory state associated with sepsis and increases blood pressure through several mechanisms, including inhibition of inducible NOS (iNOS) to reduce NO production, reversal of adrenergic receptor desensitization, and increased intravascular volume through retention of sodium and water.

**ALTERED ADRENOCEPTOR FUNCTION: IMPLICATIONS FOR CRITICALLY ILL PATIENTS**

Most of the work describing receptor function and associated clinical pharmacology has been performed in either animal models or human volunteers. In critically ill septic patients, derangements in adrenergic receptor activity may result in resistance to exogenously administered catecholamine. This “desensitization” frequently is characterized by myocardial and vascular hyporesponsiveness to high dosages of inotropes and vasopressor agents. Prolonged exposure of vascular endothelial tissue to vasopressor drugs (α-adrenergic agonists) or endogenous catecholamines may promote additional receptor downregulation. Increased endogenous catecholamine concentrations have been reported in endotoxemic and other critically ill patients, suggesting an acquired adrenergic receptor defect and desensitization of adrenergic receptors and alteration in voltage-sensitive calcium channels. The problem in critically ill patients may be related to decreased receptor activity or density. However, in patients with septic shock, catecholamine concentrations are even higher, so abnormalities in adrenergic receptor function are greater, with associated reductions in the concentrations of intracellular signal transduction mediators. The worsened receptor abnormality may be explained by defects distal to the receptor site, such as uncoupling of adrenergic receptors from adenylate cyclase or PLC, or dysfunction in the regulatory G-protein unit of signal transduction pathways.

In addition to catecholamines, circulating inflammatory cytokines may be partly responsible for distal alterations. Macrophage-derived IL-1 and TNF-α produce impaired coupling of β-adrenergic receptors to adenylate cyclase. Patients with septic shock exhibit impaired β-adrenergic receptor stimulation of cAMP associated with myocardial hyporesponsiveness to various vasopressors and inotropes. However, increased chronotropic sensitivity to β-adrenergic stimulation with hypersensitivity of the adenylate cyclase system to isoproterenol stimulation also has been reported in animal models of bacteremia and endotoxemia. In the

![Figure 30-1. Signal transduction pathways in heart and blood vessels.](image-url)
the hypothalamus, stored in the posterior pituitary, and released under normal physiologic conditions. Vasopressin is produced in the posterior pituitary, known as antidiuretic hormone, is important for osmoregulation.

**VASOPRESSIN AND CORTISOL**

Mobilizing functional cardiac reserve to maintain adequate myocardial performance. In septic shock, vasopressin concentrations remain elevated in patients with cardiogenic shock and other hypotensive states; however, vasopressin concentrations decline dramatically over the next 96 hours to a dose of synthetic ACTH irrespective of the initial serum cortisol level. Absolute insufficiency is rare, relative adrenal insufficiency is present in 50% to 70% of patients with septic shock and is associated with a poor outcome.

An elevated random cortisol concentration (>34 mcg/dL) is an independent predictor of mortality. Mortality is further increased if ACTH response is <9 mcg/dL, suggesting that the risk of mortality is greatest in situations of adrenal gland "fatigue" (i.e., degree of stress is not matched by sufficient cortisol production by the adrenals despite operating at maximal functional capacity).

**CLINICAL PHARMACOLOGY OF VASOPRESSORS AND INOTROPES**

The receptor selectivity of clinically used, catecholamine-based vaspressors and inotropes and hemodynamic effects are listed in Table 30–4. In general, these drugs are fast acting, with short durations of action. As such, these drugs are given as continuous infusions and titrated rapidly to predetermined effects. Vasopressin is administered as a replacement dosage of 0.01 to 0.04 units/min and should not be titrated. Careful monitoring and calculation of infusion rates are advised for all vaspressors because dosing adjustments are made frequently, and varying admixtures and concentrations are used in volume-restricted patients.

Dopamine has been described as having dose-related receptor activity at D_1-, D_2-, β_1-, and α_1-receptors (Table 30–4). Unfortunately, this dose–response relationship has not been confirmed in critically ill patients. In patients with septic shock, great overlap of hemodynamic effects occurs, even at dosages as low as 3 mcg/kg/min. Tachydyssrhythmias are common due to the release of endogenous norepinephrine by dopamine entering the sympathetic nerve terminal. Dopamine may increase PAOP through pulmonary vasoconstriction. This drug also may depress ventilation and worsen hypoxemia in patients dependent on the hypoxic ventilatory drive. However, it is a first-line option for the initial therapy in patients with septic shock because it increases blood pressure by increasing myocardial contractility and vasoconstriction.

Norepinephrine is a combined α- and β-agonist that produces vasoconstriction primarily via its more prominent α-effects on all
vascular beds, thus increasing SVR. Norepinephrine administration generally produces either no change or some increase in CO. In addition to dopamine, norepinephrine is considered an option for initial vasopressor therapy for septic shock.

Phenylephrine is a pure \( \alpha_1 \)-agonist and increases blood pressure through vasoconstriction. Given the presence of cardiac \( \alpha_1 \)-receptors, phenylephrine may also increase contractility and CO. It is a therapeutic option in hypotensive patients experiencing a tachyarrhythmia when a vasopressor with minimal to no \( \beta_1 \)-agonist activity is indicated.

Epinephrine exerts combined \( \alpha \)- and \( \beta \)-agonist effects. At high epinephrine infusion rates used for patients with septic shock, predominantly \( \alpha \)-adrenergic effects are observed, and SVR and MAP are increased. While epinephrine traditionally has been reserved as the vasopressor of last resort due to peripheral vasoconstriction, particularly in the splanchnic and renal beds, it is considered second-line therapy according to the current guidelines. It is widely used in other countries where other agents may not be readily available or are relatively expensive.

Dobutamine, a synthetic catecholamine, is primarily a selective \( \beta_1 \)-agonist with mild \( \beta_2 \)- and vascular \( \alpha_1 \)-activity, resulting in strong positive inotropic action without concomitant vasoconstriction. In comparison with dopamine, dobutamine produces a larger increase in CO and is less arrhythmogenic. Adrenoceptors in the heart are directly stimulated by the (−) isomer of dobutamine, but \( \beta_1 \) and \( \beta_2 \) activity resides in the (+) isomer. The strong inotropic action of dobutamine is a function of its structure, the additive effect of cardiac \( \alpha_1 \)- and \( \beta_1 \)-agonist activity, and a relatively weak chronotropic effect limited to the (+) isomer action of the \( \beta \)-receptors. Clinically, \( \beta_1 \)-induced vasoconstriction and the increased myocardial contractility with subsequent reflex reduction in sympathetic tone lead to a decrease in SVR. Dobutamine is used optimally for patients in low CO states with high filling pressures (e.g., CI < 3 L/min/m², left ventricular dysfunction demonstrated with echocardiography, or ScvO₂ <70%) or in those in cardiogenic shock; however, vasopressors may be needed to counteract arterial vasodilatation.

Unlike adrenergic receptor agonists, the vasoconstrictive effects of vasopressin are preserved during hypoxia and severe acidosis. Initiating vasopressin at ≤0.04 units/min in patients with septic shock increases SVR and arterial blood pressure to reduce the dose requirements of catecholamine adrenergic agents. These effects are rapid and sustained. Organ-specific vasodilatation reduces pulmonary artery pressure and may preserve cardiac and renal function. It may enhance urine production, likely due to increased glomerular filtration rate. At dosages exceeding 0.04 units/min, however, vasopressin is associated with ischemia of the mesenteric mucosa, skin, and myocardium. Limiting the dosage to a maximum of 0.04 units/min may minimize the development of these adverse effects. At present, vasopressin is not recommended as a replacement for norepinephrine or dopamine in patients with septic shock but may be considered as adjunctive therapy in patients who are refractory to catecholamine vasopressors despite adequate fluid resuscitation. If used, vasopressin should be administered at dosages not exceeding 0.04 units/min.

**CLINICAL APPLICATION**

**Resuscitation of Septic Shock**

Initial hemodynamic therapy for septic shock is the administration of intravenous fluid (20–40 mL/kg of crystalloid fluid), with the goal of attaining CVP of 8 to 12 mm Hg or 15 mm Hg in mechanically ventilated patients or patients with abdominal distension or preexisting ventricular dysfunction. Crystalloid fluids (e.g., normal saline, Ringer lactate) and colloid fluids (e.g., albumin, hydroxyethyl starch, blood products) are considered equivalent for shock resuscitation. Crystalloid fluids are generally preferred unless patients are at risk for adverse events from redistribution of intravenous fluids to extravascular tissues and/or are fluid restricted (e.g., patients with renal dysfunction, decompensated heart failure, ascites compromising diaphragmatic function). Recent data suggest hydroxyethyl starch may increase the risk of acute renal dysfunction in a dose-dependent manner and possibly enhance mortality. Its use warrants caution.

Traditional vasopressors and inotropes used for hemodynamic support of patients with hypotension refractory to fluid administration include dopamine, norepinephrine, phenylephrine epinephrine, and dobutamine. Optimizing MAP to 65 mm Hg as the goal of vasopressor therapy does not uniformly correlate with decreased...
mortality in patients with septic shock but global perfusion may be improved.\textsuperscript{17–21} Historically, significant concerns about the adverse effects of vasopressors limited their use. The past focus of achieving supranormal oxygen-transport variables also yielded poor results in patients with septic shock.\textsuperscript{23} In fact, normalization of systemic $D_O$ and $V_O$, whether spontaneously or with intervention, is associated with improved outcome and is not dependent on administration of vasopressor agents.\textsuperscript{23} Part of the inability to detect an improvement with vasopressor or inotropic therapies may result from the limited ability to quantify regional tissue perfusion. However, use of early goal-directed therapy to $MAP \geq 65$ mm Hg and $ScVO_2 \geq 70\%$ reduces mortality in patients with sepsis and septic shock.\textsuperscript{30}

### Comparative Studies of Catecholamine Vasopressors

#### 7 8 9

In a randomized study of 32 septic shock patients unresponsive to volume resuscitation, norepinephrine alone was superior to dopamine in achieving and maintaining preset hemodynamic (MAP of at least 80 mm Hg) and oxygen-transport variables for at least 6 hours (93\% vs 31\% of patients; $P < 0.001$).\textsuperscript{68} Of the 11 patients who did not respond to dopamine, 10 achieved the desired hemodynamic goal when norepinephrine was added. The authors suggested that differences between the two agents resulted from norepinephrine’s combined increase in $V_O$ and decrease in lactate concentrations due to reversal of splanchnic ischemia and efficient hepatic clearance of lactate or a preferential increase in $D_O$ to areas of greatest oxygen demand, thus optimizing $O_2$ ER. The same investigators showed in a prospective, observational cohort study of 97 adult patients with septic shock that use of norepinephrine to provide hemodynamic support was associated with a significant decrease in mortality (day 7: 28\% vs 40\%; $P < 0.005$; day 28: 55\% vs 82\%; $P < 0.001$; at hospital discharge: 62\% vs 84\%; $P < 0.001$).\textsuperscript{49} Using stepwise logistic regression analysis, norepinephrine was found to be the only factor associated with significantly improved survival ($P = 0.03$). Despite the drawback of the lack of randomization, this study is the first to demonstrate a survival benefit with any vasopressor. The results of another observational study found dopamine was an independent factor associated with ICU mortality in all 1,058 patients with shock (OR, 1.67; 95\% CI, 1.19–2.35; $P = 0.003$) and the subgroup of 462 patients with septic shock (OR, 2.05; 95\% CI, 1.25–3.37; $P = 0.005$).\textsuperscript{79} Yet another observational study of 277 patients with septic shock found dopamine to be associated with 28-day mortality (OR, 6.2; 95\% CI, 1.5–25; $P = 0.01$).\textsuperscript{71} In contrast, a fourth observational study of 458 patients with community-acquired sepsis found norepinephrine was independently associated with 28-day mortality (OR, 2.5; 95\% CI, 1.41–4.43; $P = 0.002$), whereas dopamine had no effect.\textsuperscript{72}

The results of a recent randomized study of norepinephrine and dopamine in 1,679 patients with shock unresponsive to volume resuscitation found similar 28-day mortality rates (48.5\% vs 52.5\% of patients; $P = 0.10$) although death from refractory shock tended to occur less frequently with norepinephrine (41\% vs 46\%; $P = 0.05$).\textsuperscript{72} Mortality rate was significantly lower in the subgroup of 280 patients with cardiogenic shock that received norepinephrine ($P = 0.03$). Overall, patients receiving norepinephrine had fewer arrhythmic events (12.4\% vs 24.2\%; $P < 0.001$) despite using dobutamine more frequently, had more vasopressor-free days, and were less likely to require open-label vasopressor support (20\% vs 26\%; $P < 0.001$). Limitations of this landmark study include combining heterogeneous shock etiologies (cardiogenic, septic, hypovolemic, and other), the use of a relatively conservative definition of “shock unresponsive to fluid administration” (only 1 L of crystalloid or 0.5 L of colloid), the use of open-label norepinephrine in patients with inadequate hemodynamic response to study drug regimens, and the lack of standardization of other shock therapies that affect hemodynamic variables (e.g., corticosteroids, vasopressin, dobutamine, additional fluid administration). Another recent study randomized 252 septic shock patients found statistically similar 28-day mortality rates between norepinephrine and dopamine (43\% vs 50\%; $P = 0.282$).\textsuperscript{75} Similar to the aforementioned study, arrhythmic events were less likely to occur with norepinephrine (5.3\% vs 23.3\%; $P < 0.0001$).

#### 7 9 11

Two randomized, double blind studies compared epinephrine with norepinephrine in 330 and 280 patients with septic shock, respectively.\textsuperscript{75,76} Both studies found similar 28-day mortality rates with epinephrine and norepinephrine (40\% vs 31\%; $P = 0.31$; and 22.5\% vs 26.1\%; $P = 0.48$). Time to hemodynamic recovery and vasopressor withdrawal were also similar between agents in both studies. One study found more events of tachydysrhythmias with epinephrine leading to study discontinuation.\textsuperscript{77} Both studies also showed that epinephrine was associated with lower arterial pH values and higher serum lactate concentrations over the first days of therapy, possibly demonstrating...
vascular tone in the kidney (greater vasoconstriction of the efferent arterioles than the afferent arteriole) or enhanced glomerular filtration rate. At low doses, dopamine has been shown to increase urine production as a result of enhanced renal blood flow from its D_{1}-receptor–mediated vasodilation, its D_{2}-receptor–mediated natriuretic effects (inhibition of Na^{+}/K^{+} ATP of renal tubular cells), or its β_{2}-receptor–mediated increase in cardiac index.\textsuperscript{48,50} In healthy subjects, the addition of dopamine to incremental doses of norepinephrine may blunt norepinephrine-induced renal vasoconstriction, thereby maintaining renal blood flow, natriuresis, urine production, and glomerular filtration. These effects also have been observed during the course of dopamine administration in oliguric and nonoliguric patients with septic shock. For this reason, low doses of dopamine sometimes are added to other vasopressors (e.g., norepinephrine). Tolerance to the vasodilatory effects of dopamine after 24 to 48 hours is evident in nonoliguric patients with sepsis syndrome.

Two studies have settled the debate surrounding low-dose dopamine. Friedrich et al. performed a meta-analysis to determine if low-dose dopamine reduces mortality or the need for dialysis in patients with critical illness.\textsuperscript{5} Among 61 clinical trials (N = 3,359), low-dose dopamine had no effect on mortality (RR, 0.96; 95% CI, 0.78–1.19), need for dialysis (RR, 0.93; 95% CI, 0.76–1.15), or occurrence of adverse events (RR, 1.13; 95% CI, 0.90–1.41). Low-dose dopamine improved urine production by 24% (95% CI, 14%–35%) on the first day of therapy but failed to maintain this effect on days 2 and 3. No improvements in serum creatinine concentration (4% relative increase; 95% CI, 1%–7%) and measured creatinine clearance (6% relative increase; 95% CI, 1%–11%) occurred within 24 hours of initiating dopamine. One adequately designed prospective, controlled trial has been conducted with low-dose dopamine in critically ill patients.\textsuperscript{7} Bellomo et al. randomized 328 critically ill patients with early renal dysfunction to either low-dose dopamine (2 mcg/kg/min) or placebo and found no differences in peak serum creatinine concentration (2.77 ± 1.63 mg/dL vs 2.82 ± 1.66 mg/dL), increase in serum creatinine concentration (0.7 ± 1.21 mg/dL vs 0.75 ± 1.22 mg/dL), need for renal replacement therapies (27.7% vs 24.3%), and urine production at any time point.\textsuperscript{7} On the basis of available evidence, low-dose dopamine for treatment or prevention of acute renal failure cannot be justified and should be eliminated from routine clinical use in the ICU.\textsuperscript{7}

Evidence now suggests that the etiology of acute renal failure from sepsis is due to efferent arteriole vasodilation.\textsuperscript{8} Enhanced urine production has been shown to occur in hyperdynamic shock with use of agents that constrict the efferent arteriole such as vasopressin and norepinephrine.\textsuperscript{40,50} In the randomized study of norepinephrine and dopamine by Martin et al.,\textsuperscript{48} urine production increased with norepinephrine but not with dopamine (22 ± 7 mL/h vs 189 ± 52 mL/h vs 24 ± 6 mL/h vs 8.2 ± 10 mL/h; P < 0.001). Adding norepinephrine to the dopamine group increased urine production to 107 ± 125 mL/h. An increase in urine production may be due to the localized vasoconstrictive effect of norepinephrine in the kidney (greater vasoconstriction of the efferent arteriole than the afferent arteriole) or enhanced glomerular filtration rate from increased renal perfusion pressure secondary to elevated CO and SVR. Delineating these differential effects of improved arterial blood pressure and CO from regional renal effects is difficult.

**CLINICAL CONTROVERSY: VASOPRESSIN**

Adding vasopressin reduces the dose of traditional catecholamine therapies and may improve renal function. However, the occurrence of ischemic events to digits and splanchnic circulation may be increased with vasopressin. Therefore, the lowest possible dose should be implemented if vasopressin is used.

**Corticosteroids**

Since two meta-analyses reported in 1995,\textsuperscript{57,58} several randomized controlled trials of low-dose corticosteroids in vasopressor-dependent septic shock patients have been published.\textsuperscript{58-58,62,61} These studies use moderate physiologic dosages (200–300 mg/day) of hydrocortisone. A meta-analysis of five studies (N = 465) showed that steroid therapy was associated with an overall improvement in survival rate (RR, 1.23; 95% CI, 1.01–1.50; P = 0.036) and shock reversal (RR, 1.71; 95% CI, 1.29–2.26; P < 0.001).\textsuperscript{35} These effects were beneficial in both responders and nonresponders to ACTH stimulation testing. These studies also showed that low-dose corticosteroid administration improves hemodynamics and reduces the duration of vasopressor support. All of these studies differ from earlier studies in that steroids were administered at lower
total doses (hydrocortisone equivalents: 1,209 mg vs 23,975 mg; \(P = 0.01\)) starting later in septic shock (23 hours vs <2 hours; \(P = 0.02\)) for longer courses (6 days vs 1 day; \(P = 0.01\)) to patients with higher control group mortality rates (mean, 57% vs 34%; \(P = 0.06\)) who were more likely to be vasopressor dependent (100% vs 65%; \(P = 0.03\)). The relationship between corticosteroid dose and survival was linear, with survival benefit at low doses (\(P = 0.02\)). Another meta-analysis of 17 trials (\(N = 2,138\)) found similar results with long-term administration of corticosteroids associated with lower mortality in hospital (RR, 0.83; 95% CI, 0.68–1; \(P = 0.05\)) and at 28 days (RR, 0.84; 95% CI, 0.71–1; \(P = 0.05\)), reduced ICU stay by 4.49 days (95% CI, −7.04 to −1.95; \(P < 0.001\)), and greater shock reversal at 28 days (RR, 1.12; 95% CI, 1.02–1.23; \(P = 0.02\)).

The results of these meta-analyses are heavily driven by data supplied by two, somewhat discordant, studies. The first randomized 300 patients with septic shock within 8 hours of hypotension to placebo or a daily combination of hydrocortisone 50 mg IV every 6 hours and fludrocortisone 0.05 mg enterally for 7 days. Similar to the meta-analyses, use of hydrocortisone reduced 28-day mortality (OR, 0.65; 95% CI, 0.39–1.07; \(P = 0.09\)), but all the benefit was seen in patients with adrenal insufficiency (OR, 0.54; 95% CI, 0.31–0.97; \(P = 0.04\)). The placebo group was more likely to continually require vasopressor therapy (hazard ratio [HR], 1.54; 95% CI, 1.10–12.16; \(P = 0.01\)), but differences between groups were exhibited only in patients with adrenal insufficiency (HR, 1.91; 95% CI, 1.29–2.84; \(P = 0.001\)). Approximately 77% of patients were deemed adrenally insufficient. The second study randomized 499 of 800 intended subjects with severe sepsis or shock within 72 hours of presentation to placebo or hydrocortisone 50 mg IV every 6 hours for 5 days followed by a 6-day taper. Mortality rates were similar between groups (32% vs 34%), irrespective of adrenal function. Median time to shock reversal was shorter in patients receiving corticosteroid therapy (3.3 vs 5.8 days; \(P < 0.001\)), again irrespective of adrenal function. Unlike the previous study, however, only 47% of patients demonstrated adrenal insufficiency likely reflective of the entry criteria and lower overall mortality rate of the study population.

**Clinical Controversy: Corticosteroid Therapy**

Current guidelines do not suggest assessing adrenal function to determine the need for corticosteroid therapy. Instead, they recommend initiating corticosteroids when hypotension is poorly responsive to vasopressor therapy. This is controversial given the limitations and differences between studies and the undefined term of “poorly responsive.” Therefore, corticosteroid therapy may be considered in septic shock patients with adrenal insufficiency or when shock is refractory to other therapies. Several questions surround the application of corticosteroid therapy in septic patients, including use in patients taking corticosteroids prior to ICU admission, most effective dosage regimen and duration, use of corticosteroids other than hydrocortisone, and the need for coadministration of fludrocortisone.

A post hoc analysis of the large vasopressor study revealed a significant interaction between vasopressin and corticosteroids. In patients receiving vasopressin therapy, concurrent corticosteroid administration increased vasopressin concentrations by 33% to 67% over the initial 24 hours compared with patients only receiving vasopressin. The addition of corticosteroids to vasopressin was associated with reduced mortality compared with concurrent administration of corticosteroids and norepinephrine (35.9% vs 44.7%; \(P = 0.03\)). In the absence of corticosteroid therapy, however, mortality was greater with vasopressin compared with norepinephrine (33.7% vs 21.3%; \(P = 0.06\)). Similar results were reported in a retrospective, matched assessment that found lower 7-day mortality was associated with combination therapy compared with vasopressin alone (19.1% vs 52.4%; \(P = 0.02\)). This interaction warrants further investigation in studies.

**Adverse Effects**

Catecholamine vasopressors may result in adverse peripheral vasoconstrictive, metabolic, and dysrhythmic effects that limit or outweigh their positive effects on the central circulation. Norepinephrine, phe- nylephrine, and epinephrine can produce lactic acidosis secondary to excessive constriction in peripheral arterioles or enhanced glycogenolysis, or as a result of mobilization of lactate from peripheral tissues as a result of improved oxygenation. Additionally, excessive peripheral vasoconstriction may cause ischemia or necrosis of already poorly perfused tissues such as the skin and the mesenteric and splanchic circulations. Some of these profound vasoconstrictive effects have been compounded by the concurrent use of other vasopressor agents in patients with septic shock who are significantly hypovolemic. These agents may be used in the context of late septic shock, where hypotension is refractory to less selective vasoconstrictors (e.g., dopamine) such that very large doses of norepinephrine or epinephrine or phenylephrine are required but provide little or no benefit. Myocardial ischemia and dysrhythmias may occur in patients with coronary artery disease, atherosclerosis, cardiomyopathies, left ventricular hypertrophy, congestive heart failure, or underlying dysrhythmias because of their inability to tolerate \(\beta_1\) cardiac stimulation that mediates increases in CO. However, the effect usually is opposite in healthy myocardium and in young patients. \(\beta_1\) Cardiac stimulation is well tolerated, ventricular filling pressures decrease, and CO and \(D_o\) increase, with a resulting increase in peripheral perfusion. The dysrhythmic potential of the catecholamine vasopressors includes a variety of resulting atrial and ventricular arrhythmias. Sympathomimetic vasopressors also have been found to possess immunomodulatory actions, primarily mediated by \(\beta_2\)-adrenergic actions (e.g., epinep- rine) because almost all immune cells express this receptor. The actions include downregulating expression of proinflammatory cytokines such as TNF-\(\alpha\) by neutrophils, suppression of oxygen free radical production from neutrophils, and direct proapoptotic effects. Dopamine suppresses prolactin secretion from the anterior pituitary gland, which may lead to reduced T-cell responsiveness. These effects may be either beneficial or deleterious by dampening harmful effects of oxygen free radical–mediated tissue injury or by reducing neutrophilic defense against bacteria.

Vasopressor catecholamines have the potential to cause extravasation-associated tissue damage if infusions infiltrate during peripheral administration. In the event of infiltration, an \(\alpha\)-receptor antagonist such as phentolamine (10 mg in 10 mL saline) should be injected intradermally to reverse local vasoconstriction, with administration of vasopressor drugs into a large central vein.

**Dopamine**

Dopamine is the initial vasopressor used for patients with septic shock. Dosages of 5 to 10 mcg/kg/min are initiated to improve MAP. Most studies of patients with septic shock have shown that dopamine at these doses increases the cardiac index by improving contractility and heart rate, primarily from its \(\beta_1\) effects. It increases MAP and SVR as a result of both increased CO and, at higher doses (>10 mcg/kg/min), its \(\alpha_1\) effects.
The clinical utility of dopamine as a vasopressor in the setting of septic shock is limited because large dosage rates frequently are necessary to maintain CO and MAP. At dosages exceeding 20 mcg/kg/min, further improvement in cardiac performance and regional hemodynamics is limited. Its clinical use frequently is hampered by tachycardia and tachydysrhythmias, which may lead to myocardial ischemia. Although tachydysrhythmias theoretically should not be expected to occur until administration of dopamine 5 to 10 mcg/kg/min, these β-effects are observed with dosages as low as 3 mcg/kg/min. They seem to be more prevalent in patients who are inadequately resuscitated (hypovolemic), in the elderly, in those with preexisting or concurrent cardiac ischemia or dysrhythmias, and in patients currently receiving other dysrhythmogenic agents, including vasopressors and inotropes.

Dopamine increases PAOP and pulmonary shunting to decrease PaO₂. The increase in PAOP may be due to changes in diastolic volumes from decreased cardiac compliance or increased venous return to the heart by α-adrenergic receptor–mediated vasoconstriction. This may affect gas exchange and decrease PaO₂. The increase in pulmonary shunting also may result from acute enhancement of pulmonary blood flow to nonhomogeneous lung regions. Thus, dopamine should be used with caution in patients with elevated preload because the drug may worsen pulmonary edema. In the instance of high filling pressures, tachycardia, or tachydysrhythmias, dopamine should be replaced by another vasopressor and/or inotrope such as norepinephrine, dobutamine, phenylephrine, or epinephrine, depending on the desired effect.

The effect of dopamine on global oxygen-transport variables parallels the hemodynamic effects. Although dopamine improves global Do₂ in septic patients, it may compromise O₂ER in the splanchic and mesenteric circulations by α₁-mediated vasoconstriction. Splanchic blood flow and Do₂ increase with dopamine, but with no preferential increase in splanchic perfusion as a fraction of CO and systemic increases in Do₂. Large doses of dopamine worsen pHᵢ and the Pco₂ gap. This is reflected by a decrease or lack of change in regional Vo₂ and a decrease in tissue O₂ER. Dopamine at low or vasopressor dosages directly impedes gastric motility in critical illness and may aggravate gut ischemia in septic shock. Similar to high-dose administration, low-dose dopamine increases splanchic blood flow but lowers splanchnic Vo₂ in sepsis. Therefore, dopamine at all dosages impairs hepatosplanchic metabolism despite an increase in regional perfusion.

The use of dopamine as a first-line agent for septic shock may be questionable because regional hemodynamics, oxygen-transport variables, and functional parameters of improved organ perfusion are not consistently enhanced in a sustained manner and may be negatively impaired. The negative findings of low-dose dopamine use (see Low (“Renal”) Dose Dopamine above) and the deleterious effects of inotropic and vasopressor dosages of dopamine on regional hemodynamics and oxygen transport raise concern over whether dopamine should be considered the first-line vasopressor agent in patients with severe sepsis or septic shock. Until dopamine is found to have definitive deleterious clinical outcomes compared to other vasopressors, empirical use of dopamine in a hypotensive patient in whom a pulmonary arterial catheter has not been inserted and in whom the cause of hypotension—low CO or vasodilation—is yet undetermined still may be reasonable. In addition, unlike other vasopressor agents, dopamine is available as premixed ready-to-use solutions of various concentrations that can be stored in automated dispensing systems for rapid initiation.

### Norepinephrine

Use of norepinephrine as first-line therapy may be more rational than dopamine because norepinephrine is more potent and is more effective in increasing MAP. It has combined strong α₁-activity and less potent β₁-agonist effects while maintaining weak vasodilatory effects of β₂-receptor stimulation. Several retrospective analyses have demonstrated improved MAP and mortality in ICU patients with severe hypotension treated with norepinephrine either as first-line therapy or after therapeutic failure with fluid resuscitation and dopamine treatment.

Norepinephrine infusions can be titrated to preset goals of MAP (usually at least 65 mm Hg), improvement in peripheral perfusion (to restore urine production or decrease blood lactate), and/or achievement of desired oxygen-transport variables while not compromising the cardiac index. Norepinephrine 0.01 to 2 mcg/kg/min reliably and predictably improves hemodynamic parameters to “normal” or “supranormal” values in most patients with septic shock. As with other vasopressors, norepinephrine dosages exceeding those recommended by most references frequently are needed in critically ill patients with septic shock to achieve pre-determined goals. A significant increase in MAP generally is caused by an increase in SVR. In contrast to dopamine, heart rate generally does not increase significantly with norepinephrine because of diminished stimulation of cardiac β₁-receptors in septic shock and reflex bradycardia from increased SVR.

Increasing norepinephrine doses to maintain higher MAPs may increase heart rates, cardiac index, DO₂, and cutaneous blood flow but these results are inconsistent. Older patients may benefit from the combined α- and β-adrenergic effects of norepinephrine given the higher incidence of coronary disease and compromised ventricles in this patient population. By virtue of restored MAP and hence coronary perfusion, cardiac index is increased in older patients, whereas in younger patients with less coronary artery disease and a higher cardiac index at baseline, norepinephrine acts primarily as a vasopressor. In contrast to dopamine, norepinephrine does not influence PAOP.

The effect of norepinephrine on oxygen transport parameters is variable and depends on baseline values and concurrently administered vasoactive agents. In most studies of norepinephrine alone, either an increase or no change in Do₂ is seen with no change in O₂ER, particularly when Do₂ values were “supranormal” prior to therapy. Norepinephrine demonstrates either no effect or improvement in Pco₂ gap, pHᵢ, or serum lactate concentrations. Splanchic blood flow and fractional blood flow are higher with norepinephrine than either dopamine or epinephrine despite higher CO with the two latter agents.

Taken together, these data suggest that norepinephrine should be the primary vasopressor of choice in patients in septic shock because of its multiple benefits: (1) norepinephrine may decrease mortality in septic shock; (2) it reverses inappropriate vasodilation and low global oxygen extraction; (3) it attenuates myocardial depression at unchanged or increased CO and increased coronary blood flow; (4) it improves renal perfusion pressure and renal filtration; (5) it enhances splanchnic perfusion; and (6) it is less likely than other vasopressors to cause tachycardias and tachydysrhythmias.

### Phenylephrine

Despite its purported use in refractory septic shock, little information is available regarding the clinical efficacy of phenylephrine. Nevertheless, it is an attractive agent for use in sepsis because of its selective α₁-agonism with primarily vascular effects. It is generally initiated at dosages of 0.5 mcg/kg/min and can be titrated every 5 to 15 minutes to desired effects. As with other vasopressors, phenylephrine dosages required to achieve goals of therapy are significantly higher than dosages traditionally recommended for use.

Phenylephrine 0.5 to 9 mcg/kg/min, used alone or in combination with dobutamine or low doses of dopamine, improves blood
pressure and myocardial performance in fluid-resuscitated septic patients. Incremental doses of phenylephrine result in linear dose-related increases in MAP, SVR, heart rate, and stroke index when administered alone as a single agent in stable, nonhypotensive but hyperdynamic, volume-resuscitated surgical ICU patients. In septic shock, phenylephrine does not impair the cardiac index, PAOP, or peripheral perfusion. In sepsis, phenylephrine improves MAP by increasing the cardiac index through enhanced venous return to the heart (increase in CVP and stroke index) and by acting as a positive inotrope. It improves myocardial performance in hyperdynamic, normotensive septic patients but worsens myocardial performance in cardiac controls. In cardiac patients, however, myocardial performance worsens as a result of a decrease in the cardiac index and an increase in SVR. Therefore, phenylephrine use warrants caution in septic shock patients with impaired myocardial performance.

In septic shock, phenylephrine appears to increase global tissue oxygen use, although information regarding the relationship of the oxygen-transport variables with increases in MAP and cardiac index is conflicting. Increases in VO₂ appear to be dissociated from DO₂, representing an increase in O₂ER as the cardiac index remains unchanged. Increases in VO₂ may result from redistribution of blood flow to previously underperfused areas, improving oxygen use as a result of changes in MAP and SVR. Evidence of globally improved peripheral tissue perfusion is observed as lactic acid concentration declines or remains unchanged and urine production increases significantly at increased or maximal VO₂. An increased O₂ER may contribute to improved tissue response.

Few data regarding the effect of phenylephrine on regional hemodynamics and oxygen-transport variables are available. When phenylephrine replaced norepinephrine in patients with septic shock, phenylephrine selectively reduced splanchic blood flow and thus splanchic DO₂ and splanchic lactate uptake rate without changing the overall splanchic VO₂. Concomitantly, pH decreased and arterial lactate concentrations increased. Because all of these parameters normalized when norepinephrine was reinstated, these data suggest that exogenous β-adrenergic stimulation (norepinephrine) may determine hepatosplanchic perfusion and oxygen availability but not utilization in septic shock. A small study comparing phenylephrine and norepinephrine for initial vasopressor therapy did not demonstrate significant differences between agents with respect to hemodynamic profiles or indices of global and regional perfusion.

The available data on hemodynamics, oxygen-transport variables, and mortality with phenylephrine in septic shock patients may not be generalizable because of the small numbers of patients evaluated. Adverse effects, such as tachydysrhythmias, are notably infrequent with phenylephrine, particularly when it is used as a single agent or at higher doses, because phenylephrine does not exert any activity on β₁-adrenergic receptors. Whether the beneficial effects can be sustained with longer administrations of phenylephrine is unclear. Phenylephrine may be a particularly useful alternative in patients who cannot tolerate tachycardia or tachydysrhythmias with use of dopamine or norepinephrine and in patients who are refractory to dopamine or norepinephrine (because of β₁-adrenergic receptor desensitization). As with other vasopressors, phenylephrine is continued until resolution of the hemodynamic instability associated with the septic episode and is weaned when patients are clinically stable. Its use in patients with myocardial dysfunction warrants further investigation.

**Epinephrine**

By convention, epinephrine has been reserved as a last-line agent for hemodynamic support of sepsis. Epinephrine, however, may be an acceptable choice as a single agent because of its combined vasoconstrictor and inotropic effects. It is as effective as norepinephrine for blood pressure control. Epinephrine infusion rates of 0.04 to 1 mcg/kg/min alone increase hemodynamic and oxygen-transport variables to “supranormal” values without adverse effects in septic patients without coronary artery disease. Large dosages (0.5–1 mcg/min) often are required. Smaller dosages (0.10–0.50 mcg/kg/min) are effective when epinephrine is added to other vasopressors and inotropes. In addition, younger patients appear to respond better to epinephrine, possibly due to greater β-adrenergic stimulation.

Despite a linear dose–response curve with rapid improvement of hemodynamic variables and DO₂, epinephrine has deleterious effects on regional hemodynamics and oxygen utilization. Although DO₂ increases mainly as a function of increases in the cardiac index and a more variable increase in SVR, VO₂ may not increase, and O₂ER may fall. A fall in pH may be seen during epinephrine administration but the impairment in gastric mucosal perfusion can be counteracted in part by dobutamine. This may be explained by the vasodilatory effect of dobutamine on gastric mucosal microcirculation resulting in a redistribution of blood flow toward the mucosa. In contrast to other vasopressors, lactate concentrations frequently rise during epinephrine therapy resulting in variable arterial pH values. When compared with a combination of norepinephrine and dobutamine, epinephrine preferentially decreases splanchic DO₂, worsens pH, and increases systemic lactate concentration without increasing VO₂. The effects of epinephrine on absolute and fractional splanchic blood flow are more pronounced during severe shock. The increase in lactate may be a result of worsened DO₂ to the liver (and subsequent anaerobic metabolism) or to the hepatosplanchic circulation, direct increase in calorigenesis and breakdown of glycogen, or lactate mobilization. However, evidence suggests that epinephrine, in contrast to dopamine, increases the proportion of total CO delivered to the splanchic circulation, although VO₂ is not increased sufficiently. As a result, O₂ER values are usually lower with epinephrine than with other vasopressors but the concomitant administration of dobutamine helps maintain O₂ER. Of all the vasopressors, epinephrine exhibits the most pronounced capacity to induce hyperglycemia by increased gluconeogenesis and glycogenolysis with α-mediated suppression of insulin secretion.

Despite the administration of high doses, epinephrine-associated clinically important dysrhythmias or cardiac ischemia occur at variable rates irrespective of age or underlying cardiac status. Nevertheless, caution must be exercised before considering epinephrine for managing hypoperfusion in hypodynamic patients with coronary artery disease, in whom ischemia, chest pain, or myocardial infarction may result. Based on the current evidence, epinephrine should not be used as initial therapy in patients with septic shock refractory to fluid administration. Although it effectively increases CO and DO₂, it has deleterious effects on the splanchic circulation. If it is used as a second-line agent in septic shock, factors that may influence successful therapy with epinephrine include the time from onset of septic shock to effective therapy and the age of the population.

**Dobutamine**

Dobutamine is an inotrope with vasodilatory properties (an “inodilator”). It is used for treatment of septic and cardiogenic shock to increase the cardiac index, typically by 25% to 50%. In septic shock, LVEF and right ventricular function are depressed despite a high cardiac index, whereas ventricular volumes and compliance are increased. Stroke index is maintained by an increased heart rate and ventricular dilation. In survivors, myocardial depression is reversible and normalizes 5 to 10 days after the onset of sepsis. Dobutamine increases stroke index, left ventricular stroke work index, and thus cardiac index and DO₂ without increasing...
The ability of dobutamine to enhance cardiac index and $D_O_2$ during septic shock appears to be related to its chronotropic effect. However, dosage increments of dobutamine beyond 20 mcg/kg/min are limited by complications of tachycardia, ischemic changes on electrocardiogram, hypertension, and tachydysrhythmias despite the absence of preexisting cardiac abnormalities. Of note, the combination of dobutamine and norepinephrine results in a lower increase in heart rate compared with use of other vasopressors alone.

Increased cardiac performance measures in response to adjunctive dobutamine therapy are predictive of survival during sepsis. However, the achievement of supranormal oxygen transport values with dobutamine is of little value compared with treatment to normal values. In addition, administration of dobutamine to achieve these high values may increase mortality rate and/or the incidence of adverse effects. Dobutamine increases $D_O_2$ without affecting $VO_2$, resulting in decreased OER. Arterial lactate concentrations decrease significantly with norepinephrine and dobutamine compared with dopamine and epinephrine infusions.

Studies have focused on the effects of dobutamine on gastric mucosal flow and the splanchnic circulation. The addition of dobutamine to other vasopressors improves gastric mucosal perfusion without increasing the cardiac index. This is consistent with findings that dobutamine may improve pH and mucosal perfusion in septic patients. The addition of dobutamine to norepinephrine or epinephrine treatment improves gastric mucosal perfusion as measured by improvements in $pH$, and $P_CO_2$ gap. This effect may relate to blood flow redistribution toward gastric mucosa, due to either an increase in the fraction of $CO$ distributed to the global hepatosplanchnic blood flow and/or a redistribution of blood flow within gastric wall layers toward the mucosa by “stealing” blood away from the muscularis potentially as a result of greater $\beta_1$-mediated vasodilation. Sublingual microcirculation improves after dobutamine is added to vasopressor-dependent septic shock patients in a manner unrelated to arterial pressure or cardiac index, suggesting that enhanced perfusion is the result of the “steal” phenomenon. Of note, gastric mucosal perfusion and tissue oxygen utilization are most improved with concurrent norepinephrine and dobutamine therapies compared with other vasopressor combinations at the same level of MAP.

Dobutamine should be started at dosages ranging from 2.5 to 5 mcg/kg/min. In the study of early goal-directed therapy, dobutamine was administered to 13.7% of patients within 6 hours of resuscitation to achieve $ScVO_2 ≥70%$. Although a dose response may be seen, evidence now suggests that dosages ≥5 mcg/kg/min may provide limited beneficial effects on oxygen transport values and hemodynamics and may increase adverse cardiac effects. If given to patients who are intravascularly depleted, dobutamine will result in hypotension and a reflexive tachycardia. Pathophysiologic factors influence dosing requirements and pharmacokinetic parameters over the time course of the illness and the duration of the infusion. Decreases in $P_AO_2$, as well as myocardial adverse effects such as tachycardia, ischemic changes on electrocardiogram, tachydysrhythmias, and hypotension are seen. Thus, infusion rates should be guided by clinical end points and $S_VO_2/ScVO_2$. Dobutamine, like other inotropes, usually is given until improvement in myocardial function with resolution of the septic episode or dose-limited side effects are observed.

**Vasopressin**

Studies involving vasopressin infusion for management of septic shock show rapid and sustained improvement in hemodynamic parameters. These effects are evident with administration of dosages not exceeding 0.04 units/min. Administration of dosages >0.04 units/min and 0.05 units/min are associated with negative changes in $CO$ and mesenteric mucosal perfusion, respectively. The reduction in $CO$ likely is the result of lowered stroke volume.

Vasopressin’s strongest vasoconstrictive action occurs in the skin and soft tissues, skeletal muscles, and fat tissues. As a result, ischemic skin lesions have been observed in several studies, with an occurrence rate as high as 30% after vasopressin was added to norepinephrine-resistant shock. Although vasopressin may have deleterious effects on mesenteric and skin perfusion, studies report vasodilatation of cerebral, pulmonary, coronary, and some renal vascular beds. The clinical outcomes associated with selective vasodilation are not yet determined except for the possibility of enhanced urine production in patients not anuric at baseline.

In order to minimize the potential for adverse events and maximize the beneficial effects, vasopressin should be used as add-on therapy to one or two catecholamine adrenergic agents rather than as first-line therapy or salvage therapy and dosages should be limited to 0.04 units/min. The results of studies showed that vasopressin markedly reduced the requirements for adrenergic agents, but few studies demonstrated complete discontinuation of these therapies. Therefore, vasopressin should be used only if response to one or two adrenergic agents is inadequate or as a method for reducing the dosage of these therapies. Increased arterial pressure should be evident within the first hour of vasopressin therapy, at which time the dose(s) of adrenergic agent(s) should be reduced while maintaining blood pressure. This method should help limit the degree of ischemia.

Most studies evaluated vasopressin use for <48 hours, and several studies reported difficulty discontinuing vasopressin therapy. Whether additional benefits, deleterious effects, or tolerance is observed with longer infusions remains unclear. Long-term administration of vasopressin is associated with hyponatremia and thrombocytopenia. Because vasopressin is being used to replace a physiologic deficiency, it stands to reason that the requirement for vasopressin will subside with reversal of the septic process. Attempts to discontinue vasopressin should occur when the dosage(s) of adrenergic agent(s) has been minimized (e.g., dopamine ≤5 mcg/kg/min, norepinephrine ≤0.1 mcg/kg/min, phenylephrine ≤1 mcg/kg/min, epinephrine ≤0.15 mcg/kg/min). At present, vasopressin should not be initiated as first-line therapy or added to existing therapy solely because a patient is septic.

**Corticosteroids**

Corticosteroids can be initiated in cases of septic shock when adrenal insufficiency is present or when weaning of vasopressor therapy proves futile. Adverse events are few because corticosteroids are administered for a finite period of time, usually 7 days.
Acutely, elevated serum concentrations of blood urea nitrogen, white blood cell count, and glucose occur. Although long-term administration of corticosteroids is associated with several chronic disease states, meta-analyses do not show an increase in adverse events, including gastrointestinal hemorrhage (RR, 1.12; 95% CI, 0.81–1.53; P = 0.5), superinfections (RR, 1.01; 95% CI, 0.82–1.25; P = 0.92), and neuromuscular weakness (RR, 0.63; 95% CI, 0.12–3.35; P = 0.58).\textsuperscript{55,56} Hyperglycemia (RR, 1.16; 95% CI, 1.07–1.25; P <0.001) and hypernatremia (RR, 1.61; 95% CI, 1.26–2.06; P <0.001) are associated with corticosteroid therapy.\textsuperscript{55,56} Therefore, therapy of septic shock with corticosteroids improves hemodynamic variables and lowers catecholamine vasopressor dosages with minimal to no effect on patient safety.\textsuperscript{7}

### EXPERIMENTAL THERAPIES

#### NITRIC OXIDE INHIBITORS

NO is a short-acting, potent vasodilator derived from enzymatic oxidation of arginine. Its production is under control of NOS. This enzyme is present (expressed) in two forms: a constitutive form (eNOS) and an inducible form (iNOS). Small amounts of NO normally are produced by the vascular endothelium under the control of eNOS for physiologic control of vascular tone and blood flow distribution. Under pathophysiologic conditions such as stimulation by lipopolysaccharide or cytokines, iNOS becomes diffusely expressed, producing large amounts of NO. The latter has been implicated in the cardiovascular failure of septic shock.

Pharmacologic inhibition of NO production has been investigated as an adjunct to standard therapies of septic shock. L-Arginine analogs such as monomethyl-L-arginine (L-NMMA) and L-arginine-methylester (L-NAME) are competitive inhibitors of NOS and have been shown to increase blood pressure, partially restore vascular reactivity, and reduce vasopressor use.\textsuperscript{7,11,12} However, because these arginine analogs nonselectively block eNOS and iNOS, their use has been associated with extensive vasoconstriction, decreased CO, and regional hyperperfusion, thus promoting organ failure and mortality. Some S-substituted thiourea derivatives have demonstrated, both in vitro and in vivo (rodent), dose-dependent selectivity for iNOS inhibition, but the clinical application must be evaluated. A phase I/IIa clinical trial of septic shock patients is underway (see www.medinox.com).

Pyridoxalated hemoglobin polyoxyethylene is a scavenger of NO. A phase II study of 62 patients with vasodilatory shock requiring vasopressors showed that an infusion of 20 mg/kg/h for up to 100 hours rapidly increases blood pressure and shortens the duration of vasopressor therapy.\textsuperscript{42} Additional studies are needed.

#### METHYLENE BLUE

Methylene blue counteracts eNOS, iNOS, and soluble guanylate cyclase to reduce serum concentrations of NO and cyclic guanosine monophosphate.\textsuperscript{43} Despite these effects, methylene blue does not alter the expression of inflammatory cytokines. Clinically, methylene blue at dosages of 0.25 to 3 mg/kg/h increases SVR, MAP, myocardial contractility, and DO\textsubscript{2} in septic shock patients refractory to vasopressors.\textsuperscript{45} It may increase pulmonary vascular resistance, potentially worsening oxygenation. Additional studies are needed before methylene blue can be recommended; at present, it has been used only for salvage therapy.

#### TERLIPRESSIN

Terlipressin, a prodrug that is converted into lysine vasopressin, has been used in septic shock patients and is available in other countries.\textsuperscript{46} This drug has a half-life of 6 hours and acts via vascular V\textsubscript{1} receptors and renal tubular V\textsubscript{2} receptors. Terlipressin increases MAP to a greater extent than norepinephrine when it is used as the initial vasopressor in septic shock. Despite a decrease in CO, heart rate, and DO\textsubscript{2}, terlipressin increases gastric mesenteric perfusion, urine production, and creatinine clearance while reducing lactate concentration. Both terlipressin and vasopressin increase blood pressure and decrease heart rate to the same extent but terlipressin is associated with less supplemental norepinephrine usage and improved mesenteric perfusion.\textsuperscript{85,86} These preliminary findings suggest that a clinical trial evaluating mortality as well as hemodynamic effects should be conducted.

### LEVOSIMENDAN

Levosimendan is a novel inotropic and vasodilator calcium-sensitizing drug.\textsuperscript{87} In acute decompensated heart failure, it improves cardiac contractility by sensitizing troponin C to calcium. In septic shock patients with and without left ventricular dysfunction, levosimendan 0.1 to 0.2 mcg/kg/min decreases PAOP, increases LVEF and cardiac index, improves mesenteric perfusion, and enhances urine production.\textsuperscript{87} Levosimendan improves Scvo\textsubscript{2} to the same extent as dobutamine when it is used in early goal-directed therapy. Levosimendan is associated with declining serum lactate concentration. While additional clinical trials of levosimendan in septic shock are needed, increased mortality was demonstrated in studies of acute decompensated heart failure.

### DOPEXAMINE AND ISOPROTERENOL

Dopexamine is a structural and synthetic analog of dopamine that exerts systemic vasodilation through stimulation of β\textsubscript{2}-adrenoceptors and peripheral D\textsubscript{1} and D\textsubscript{2} receptors and weak inotropic properties through stimulation of β\textsubscript{2}-adrenoceptors.\textsuperscript{49,50} It has been used in patients with acute heart failure and septic shock. Similar to dobutamine, dopexamine is administered in combination with a vasopressor in septic shock. In small studies of septic shock, dopexamine produced a dose-related (range, 2–6 mcg/kg/min) increase in cardiac index, stroke volume, and heart rate, as well as a decrease in SVR over the course of 0.5 to 1 hour while the dosages of other vaspressors were kept constant. The increase in myocardial oxygen demand is less than with dopamine, but tachycardia and tachydyssrhythmia may lead to myocardial ischemia, especially when ischemic heart disease is present. Global oxygen transport variables are similar to those of dopamine: DO\textsubscript{2} increases but VO\textsubscript{2} increases insufficiently, resulting in impaired O\textsubscript{2}ER. The combined β\textsubscript{2}-adrenoceptors and peripheral D\textsubscript{1} agonistic effects of dopexamine should improve distribution of blood flow. However, the results of studies of dopexamine use in septic shock failed to show preferential increase in splanchnic blood flow. In fact, gastric pH\textsubscript{i} was lowered. When administered over 7 days, dopexamine had no impact on renal function. Therefore, initial data do not support a role for dopexamine in improving regional hemodynamics and blood flow, but studies continue to investigate dopexamine as an alternative therapy for septic shock.

Isoproterenol is a synthetic catecholamine that stimulates only β\textsubscript{1}- and β\textsubscript{2}-adrenoceptors to produce vasodilatory and inotropic effects.\textsuperscript{88} Although not thought of as a traditional agent for managing septic shock, isoproterenol has received attention because of the concepts of early goal-directed therapy.\textsuperscript{30} The strong β\textsubscript{1}-adrenergic effects of isoproterenol make it a potential alternative to dobutamine for optimizing DO\textsubscript{2} in patients with low Svo\textsubscript{2}, despite use of other therapies (e.g., fluid resuscitation, vasopressors, red blood cell transfusion). In patients with septic shock and Svo\textsubscript{2} <70% despite volume administration, norepinephrine, and red blood cell transfusion, adding isoproterenol increases Svo\textsubscript{2}, cardiac index, and stroke...
index while decreasing lactate concentration without increasing heart rate or causing myocardial ischemia. Although these results are intriguing, additional studies are needed to define the role of isoproterenol, especially considering that dobutamine has become standard therapy for early goal-directed therapy. At present, isoproterenol is an agent of last resort.

OTHER THERAPIES

As with vasopressin and cortisol, critical illness impairs hypothalamic-pituitary function, producing relative deficiencies of triiodothyronine (T₃) and thyroxine (T₄). This condition, referred to as euthyroid sick syndrome, may contribute to hypotension. Concentrations of thyrotropin-releasing hormone and thyroid-stimulating hormone are inappropriately low. Measured concentrations of free T₃ and T₄ may be low or normal, but synthesis is consistently impaired. Only scant data regarding the replacement of these hormones in critically ill patients are available, and the results are variable, depending on the extent of additional hormone replacement (growth hormone, gonadotropin-releasing hormone, leptin, insulin, thyrotropin-releasing hormone, and thyroid-stimulating hormone). Given the data for replacing vasopressin and cortisol in septic shock, it is reasonable to assume that one day a "thyroid replacement" regimen will be offered as an adjunctive treatment to vasopressors.

Drotrecogin alfa (activated) or recombinant activated protein C has been established as a treatment of severe sepsis because it reduces mortality when used early in patients with at least two organ dysfunctions or an Acute Physiology and Chronic Health Evaluation (APACHE) II score of 25. Drotrecogin alfa (activated) promotes fibrinolysis, inhibits coagulation, and modulates inflammation. It inhibits inflammation, possibly preventing endotoxin-induced hypotension. A study of 22 septic shock patients treated with drotrecogin alfa (activated) showed that the norepinephrine dosage rate decreased 33% over 24 hours. In contrast, the norepinephrine dosage increased 38% in the matched control group despite MAP values similar to the drotrecogin alfa (activated) group. Although these results deserve further investigation, drotrecogin alfa (activated) likely will never be administered solely for hemodynamic support of septic shock patients because it is an expensive agent with concerns of hemorrhage as a side effect. Ultimately, patients who “qualify” for drotrecogin alfa (activated) will receive it irrespective of hemodynamic effect.

GENERAL CONCLUSIONS AND RECOMMENDATIONS

The choice of vasopressor or inotropic agent in septic shock should be made according to the needs of the patient. Figure 30–2 presents an algorithm for the management of septic shock. This algorithm suggests a stepwise approach, first using dopamine or norepinephrine. Dobutamine is added for low CO states or to optimize SVO₂/SvO₂. Occasionally, epinephrine and phenylephrine are used when necessary. Although this approach is empirical, it is used...
broadly in clinical practice and has been justified by the desire to avoid strong vasoconstriction. However, observations of improved outcomes with norepinephrine and decreased regional perfusion with dopamine are calling into question the use of dopamine as a first-line agent. Most clinicians now prefer norepinephrine as the initial vasopressor agent. Developing a strategy to titrate therapy early in the course of illness to predetermined values reduces mortality. Goals of initial resuscitation should include fluids to achieve CVP 8 to 12 mm Hg, vasopressor agents to achieve MAP at least 65 mm Hg, red blood cell transfusion to maintain hematocrit ≥30%, and inotropic therapy to achieve ScvO₂ ≥70%.

For all catecholamine vasopressors, doses higher than recommended traditionally are required for goal-directed therapy to MAP and for normalization of oxygen-transport variables, D O₂ and V O₂. Patients who develop supranormal D O₂ and V O₂ values have lower mortality, but whether this effect is achieved intrinsically or with exogenous administration of vasopressors/inotropes appears inconsequential. Therefore, goal-directed therapy to supranormal oxygen-transport variables cannot be recommended because little or no benefit has been demonstrated. Further work is required to better elucidate the differential effects of vasopressors on regional hemodynamic and oxygen-transport values as measures of local tissue perfusion.

The algorithmic approach (Fig. 30–2) we recommend for use of vasopressors and inotropes in the hemodynamic support of critically ill septic patients is consistent with the recommendations made in the Surviving Sepsis Campaign® and the American College of Critical Care Medicine’s guidelines to the hemodynamic support of adult patients with sepsis (Table 30–2). Although difficult to demonstrate, true differences in clinical outcomes as a result of differences in the pharmacologic activity of vasopressors and inotropes may exist. For example, evidence suggests that norepinephrine, when used appropriately with fluid replenishment, is safe and effective in treating septic shock; it decreases mortality, particularly when started early in the course of septic shock. It is effective in optimizing hemodynamic variables and improving systemic and regional (e.g., renal, gastric mucosal, and splanchnic) perfusion. Epinephrine causes a greater increase in the cardiac index and D O₂ and increases gastric mucosal flow but may not preserve splanchnic circulation adequately. It may cause increases in lactic acid. Epinephrine may be particularly useful when used earlier in the course of septic shock in young patients. Unlike epinephrine, dopamine does not increase the proportion of CO that preferentially goes to the splanchnic circulation. The ability of dopamine to increase CO by no more than 35% accompanied by a tachycardia or tachydysrhythmias limits its utility. Dopamine, as opposed to norepinephrine, has been shown to worsen splanchnic V O₂ and O₂ER and is of limited value in improving urine production. Low-dose dopamine has not been shown consistently to increase the glomerular filtration rate, does not prevent renal failure, and actually worsens splanchnic tissue oxygen utilization. Low-dose dopamine should not be used. Phenylephrine should be used when a pure vasoconstrictor is desired in patients who may not require or cannot tolerate the β-effects of dopamine or norepinephrine with or without dobutamine. In patients with a high filling pressure and hypotension, the combination of phenylephrine and dobutamine may be useful.

Shortcomings of study methodology prevent the establishment of definitive conclusions. As a consequence, published guidelines for the management of severe sepsis and septic shock have many inconclusive recommendations (Table 30–2). Short infusions during studies may show differences that are not clinically significant after 24 hours, as demonstrated for epinephrine and dobutamine. Clinically, vasopressors and inotropes are used for hours to days. Possible confounding factors are the variable times at which studies are initiated with respect to the stage of sepsis or septic shock, the inherent differences in circulating catecholamine concentrations, changes in receptor activity, as well as differences in prestudy duration and type of exogenous catecholamine administration.

Initial studies with vasopressin suggest a potential role in the management of vasopressor-dependent septic shock patients. Vasopressin appears to reduce the requirements of adrenergic agents while maintaining hemodynamic function. While it may enhance urine production, it is associated with mesenteric and peripheral ischemia. Therefore, vasopressin should be used only if response to one or two adrenergic agents is inadequate or as a method for reducing the dosage of these therapies. Close monitoring of ischemic events is needed. Data indicate that moderate doses of hydrocortisone (200–300 mg/day) administered over several days may reverse septic shock and dependency on vasopressor agents, particularly in patients with relative adrenal insufficiency. As a result of a recent multicenter study, the presence of adrenal insufficiency to indicate therapy with corticosteroids is controversial. Given the discrepancy of the current data, corticosteroids may be administered to patients with septic shock refractory to vasopressors or when adrenal insufficiency is present. Data on optimal dosing regimens and definitive outcomes still are needed.

Further pharmacotherapeutic and outcomes studies are required to elucidate the place in therapy of individual vasopressors and inotropes or their combinations in the supportive care of patients with bacteremia or septic shock. As supportive therapy, it is imperative that primary therapy aimed at the source of (antimicrobials) infection be initiated quickly to afford the patient the best chance of survival. Once this goal is accomplished, we will need to direct our efforts to pharmacoeconomics and the cost effectiveness of these therapies.

**ABBREVIATIONS**

ACTH: adrenocorticotropic hormone  
APACHE: Acute Physiology and Chronic Health Evaluation  
ATP: adenosine triphosphate  
CaMK: calcium-calmodulin-dependent protein kinase  
cAMP: cyclic adenosine monophosphate  
Cao₂: arterial oxygen content  
CI: confidence interval  
CO: cardiac output  
CO₂: carbon dioxide  
Cvo₂: venous oxygen content  
CVP: central venous pressure  
D O₂: oxygen delivery  
D O₂I: oxygen delivery index  
ecNOS: constitutive nitric oxide synthase  
HR: hazard ratio  
ICU: intensive care unit  
IL: interleukin  
iNOS: inducible nitric oxide synthase  
I-NAME: l-arginine-methylester  
I-NMMA: monomethyl-l-arginine  
LVEF: left ventricular ejection fraction  
MAP: mean arterial pressure  
NO: nitric oxide  
NOS: nitric oxide synthase
O_{ER}: oxygen extraction ratio
OR: odds ratio
Paco_{2}: arterial carbon dioxide pressure (tension)
Pao_{2}: arterial oxygen pressure (tension)
PAOP: pulmonary artery occlusion pressure
Pco_{2}: gut luminal partial pressure of carbon dioxide
pH: intramucosal pH
PLC: phospholipase
Psco_{2}: sublingual carbon dioxide pressure
RR: relative risk
Sa{o}_{2}: arterial oxygen saturation
SVR: systemic vascular resistance
T_{3}: triiodothyronine
T_{4}: thyroxine
TNF: tumor necrosis factor
VO_{2}: oxygen consumption
VO_{2}I: oxygen consumption index

KEY CONCEPTS

1. Plasma does not have to be lost from the body for hypovolemic shock to occur.
2. Patients may die of hypovolemic shock despite having normal serum electrolyte concentrations.
3. Although the Starling equation of fluid transport is useful for understanding the factors involved in fluid shifting between compartments, it is not a practical tool for use in the clinical setting.
4. Patients may have complications and death as a result of reperfusion injury as well as the initial insult.
5. The clinical presentation of patients with hypovolemic shock can vary substantially, depending on concomitant disease states, medications, and cause of hypovolemia.
6. The initial monitoring of a patient with suspected intravascular depletion always should include vital signs, urine output, mental status, and physical examination.
7. The need for intravenous (versus oral) rehydration in children often is overestimated.
8. Crystalloid (sodium-containing) solutions should be used for most forms of circulatory insufficiency that are associated with hemodynamic instability.
9. Neither crystalloids nor colloids have the oxygen-carrying properties of red blood cells.
10. Vasoactive medications should not be considered for hypovolemic shock until fluid resuscitation has been optimized.

EPIDEMIOLOGY

Because shock is not a reportable category by state and federal agencies that track causes of death, the incidence is unknown. Estimates of deaths due to shock are complicated by differences in definitions and classification systems. Part of the problem is defining when progressive circulatory insufficiency results in the loss of normal compensatory responses by the body, which could reverse the processes leading to irreversible organ dysfunction. This loss of appropriate compensation varies from patient to patient and is not always readily apparent during the initial patient presentation. Therefore, forms of hypovolemic shock, such as hemorrhagic shock, are subsumed by more readily identifiable categories of death, such as accidental injuries and homicides. Crude and conservative estimates of death due to hypovolemic shock are available for some of its forms. More than 100,000 deaths each year in the United States are due to unintentional injuries that frequently involve bleeding, and approximately 5,000 deaths are due to hyperthermia and dehydration associated with heat exposure. The figures are much higher when considered on a global basis. For example, electrolyte depletion and dehydration due to diarrheal disease result in approximately 2 million deaths each year in children younger than 5 years. The most liberal estimates of death include all causes of circulatory failure (i.e., the last stage of shock).

ETIOLOGY

1. Hypovolemic shock may result from blood loss (plasma and red blood cells) due to trauma, surgery, or internal hemorrhage or from plasma loss due to fluid sequestered within the body or lost from the body (Table 31–1). In some cases, such as in

*Shock may result from various combinations of blood and plasma volume losses listed (i.e., causes are not mutually exclusive).
postoperative patients, a number of these problems occur at the same time. For example, a patient may have blood loss secondary to trauma or surgery, with additional fluid being third spaced (e.g., as tissue edema in the gastrointestinal tract with a concomitant ileus) and lost through a high-output gastrointestinal fistula postoperatively. As this example of third-spaced fluid indicates, fluid (i.e., plasma) does not have to be lost from the body for a person to develop hypovolemic shock, although the fistula output would clearly aggravate the situation. Approximately 20 L of fluid is secreted and reabsorbed daily in the gastrointestinal tract, so it is not surprising that volume loss could be substantial, depending on the location of the fistula and function of the tract preceding the fistula.

Dehydration may result from primary water deficiency, usually because of decreased intake, but in some instances (e.g., diabetes insipidus) may result from increased losses of water. With most forms of dehydration, such as those caused by diarrheal disease and heat-related illness, a combination of inadequate intake and higher than normal losses occurs. In general, the term dehydration implies primary intracellular water depletion, in contrast to volume depletion, which implies extracellular, and particularly intravascular, sodium and water loss. However, there is substantial overlap in the definitions and use of terms such as dehydration and volume depletion in the medical literature, so the reader must be cognizant of the intended meaning. In the case of primary water deficit, cell dehydration occurs. Initially, the patient may be thirsty and possibly have some mental status changes, such as confusion. If cellular dehydration occurs slowly, intracellular substances, referred to as idiogenic osmols, develop that limit progressive complications (e.g., cerebral edema or coma). Death due to primary water deficit, if it occurs, is usually a result of delayed circulatory failure. With combined water and salt deficiencies, such as might occur with gastrointestinal (e.g., diarrhea) and skin losses (e.g., heat stroke), interstitial and intravascular depletion is an early occurrence. Fortunately, dehydration is relatively easy to prevent with routine vigilance and water replacement compared with some of the other causes of shock.

**PATHOPHYSIOLOGY**

Hypovolemic shock often is described in terms of monitoring parameters such as lowered blood pressure, but patients with shock may die despite normal surrogate markers of circulatory insufficiency. Therefore, an appropriate definition should mention the underlying problem, which is inadequate tissue perfusion resulting from circulatory failure. In the case of hypovolemic shock, the cause of the altered perfusion is fluid (or volume) depletion resulting from trauma, surgery, thermal injury, or some form of dehydration. Figure 31–1 provides a simplified view of the pathophysiology of circulatory insufficiency assuming the acute insult causing the plasma volume depletion did not result in immediate patient death.

Cell damage and death may occur from the primary insult or from reperfusion injury. The latter problem is associated most frequently with trauma and blood loss that cause a systemic inflammatory response syndrome (SIRS) with the release of a multitude of mediators of inflammation and injury that have complex interactions. Cells have varying responses to hypoxia, ranging from astrocytes that quit functioning almost immediately to hepatic cells that may function for several hours after injury to skin, muscle, and bone cells that may tolerate prolonged periods of hypoperfusion.4,5 Left unmitigated, cell death occurs with prolonged injury and is usually heralded by acidosis, hypothermia, and coagulopathy—referred to as the lethal triad.5

The body attempts to compensate for volume depletion beginning with autoregulatory changes involving smaller blood vessels. When the cause of circulatory insufficiency continues unabated, local mechanisms eventually fail to provide adequate compensation, and macrocirculatory changes ensue. Approximately 75% of blood volume is contained in venous capacitance vessels, with gravity being the major impedance to flow back to the heart.4 With increasing volume depletion, blood flow to the heart (preload) is decreased, with subsequent activation of baroreceptors and chemoreceptors leading to sympathetic discharge. Also, fluid shifting from the interstitial space to the intravascular space occurs through a phenomenon known as transcapillary refill, and hormones (e.g., adrenocorticotropic hormone, angiotensin, catecholamines, and vasopressin) that cause sodium and water retention by the kidneys are released. The phenomenon of transcapillary refill means that the body can have fluid losses exceeding normal plasma volume. These responses cause alterations in stroke volume, heart rate, and peripheral vascular resistance so that blood pressure and hence tissue perfusion can be maintained.

The microcirculatory changes associated with shock are complex and difficult to study. Although some mediators such as catecholamines, angiotensin II, arginine vasopressin, and endothelin-1 cause vasoconstriction, other mediators, such as adenosine and nitric oxide, yield vasodilation. These changes result in hypoperfusion or hyperperfusion, depending on the organs involved. As these microcirculatory changes fail to maintain adequate organ

**FIGURE 31-1.** Pathophysiology of circulatory insufficiency.
perfusion, more widespread sympathetic nervous system activation and vasoconstriction ensue. Even assuming general circulation is restored, capillaries may not function properly due to ongoing edema and ischemia. Failure to respond to sympathetic stimulation and fluid administration is indicative of the vasodilation that occurs in the final phase of circulatory failure leading to death.

The factors involved in fluid shifting between the intravascular and interstitial spaces are described by the modified Starling equation:

$$J_v = K_f,c \cdot (P_c - P_t) - \sigma (\pi_c - \pi_t)$$

where $J_v$ = net transvascular flow rate (cannot be measured in the clinical setting)

$K_f,c$ = capillary filtration coefficient for fluids (cannot be measured in the clinical setting)

$P_c$ = capillary hydrostatic pressure (indirectly estimated in the clinical setting, e.g., pulmonary artery occlusive pressure)

$P_t$ = tissue hydrostatic pressure (cannot be measured in the clinical setting)

$\sigma$ = reflection coefficient for proteins (cannot be measured in the clinical setting)

$\pi_c$ = plasma colloid osmotic pressure (not usually measured in the clinical setting, but technology is available)

$\pi_t$ = tissue colloid osmotic pressure (cannot be measured in the clinical setting)

Proteins act as oncotic agents in each of these spaces to attract fluid, whereas hydrostatic forces push fluid into or out of the vessels. The equation has distinct permeability values for water and protein because each crosses the vascular membrane at a different rate. The values for the variables listed in the equation are not the same for capillaries in all parts of the body. For example, on a scale from 0 to 1 with 0 being free passage of protein and 1 being impermeable to protein, the typical value for the reflection coefficient in most capillaries is >0.9. However, in the pulmonary capillaries the value is closer to 0.7 and approaches 0 in inflammatory states associated with increased capillary permeability. As the value approaches 0, the capillaries are freely permeable not only to the usual fluid and electrolytes but to plasma proteins such as albumin. Because albumin accounts for approximately 80% of the plasma oncotic pressure, its free passage into the interstitial space effectively negates its intravascular oncotic benefit. Although the Starling equation is useful to practitioners in terms of understanding the factors involved in fluid shifting between compartments, the rate and direction of transvascular flow cannot be calculated accurately in the clinical setting because most factors cannot be measured directly and the values for the factors vary in different capillaries in the body.

The body’s compensatory mechanisms may have beneficial and harmful consequences. For example, cardiac output can be increased substantially by increases in stroke volume or heart rate. Although this may be useful for providing blood flow to inadequately perfused tissues, it may cause large increases in oxygen consumption by the heart that could aggravate preexisting ischemia in patients with underlying coronary artery disease (CAD). Another example is the sympathetic nervous system–mediated vasoconstriction that causes blood to shift from the skin, skeletal muscle, and some internal organs such as the kidneys and gastrointestinal tract to organs (e.g., heart and brain) that are less tolerant of inadequate flow. If the vasoconstriction continues unabated, the hypoperfused organs eventually become damaged. Figure 31–2 provides an overview of the compensatory changes that occur with a loss of circulating blood volume.

**FIGURE 31-2.** Activation of compensatory mechanisms with loss of circulatory volume. Certain stages may be absent, depending on a number of factors, such as age, preexisting disease states, and cause of circulatory insufficiency. (ACTH, adrenocorticotropic; BP, blood pressure; CO, cardiac output; HR, heart rate; PVR, peripheral vascular resistance; RR, respiratory rate.)
4 In addition to the more acute implications of hypovolemia and attendant complications, reperfusion damage is likely to occur, particularly after prolonged resuscitation attempts. In addition to edematous obstruction of capillaries and oxygen-free radical damage of cell membranes, a number of cellular (e.g., white blood cells and platelets) and humoral (e.g., procoagulants, anticoagulants, complement, and kinins) components are activated, causing the release of other inflammatory mediators. The resulting reperfusion injury may range from readily reversible organ dysfunction to multiple-organ failure and death. The lungs are frequently the first system affected either by excessive fluid resuscitation or by the mediators of secondary reperfusion injury. The latter form of injury often results in the most severe form of acute lung injury known as the acute respiratory distress syndrome that is defined by an arterial oxygen tension: fraction of inspired oxygen ratio of less than 200 in the absence of hypervolemia.

Although the basic pathophysiology is similar for the various causes of hypovolemic shock, there are unique considerations relative to each. For example, whereas isolated head injuries associated with trauma typically do not result in substantial blood loss or shock, long bone or pelvic fractures may sequester several liters of blood. Patients with traumatic or thermal injuries, as well as postoperative patients, may have substantial fluid accumulation in sites where the fluid cannot be readily transferred back into blood vessels (i.e., third-spaced fluid) for maintaining pressure. With these types of injuries, prompt control of compressible bleeding sources with rapid patient transfer to the hospital for definitive treatment may preclude the cascade of events leading to shock. Indeed, with trauma patients, a “scoop and run” approach that places a priority on rapid transport to a hospital is used by most urban hospitals.

In the case of hemorrhagic shock, prompt attention must be given to cell as well as plasma losses. Red blood cells lost during the bleeding episode may lead to ischemic damage in vital organs. Packed red blood cell transfusions may be needed to increase the oxygen-carrying capacity of the blood because oxygen transport is a function not only of cardiac output but also of hemoglobin concentration and saturation and of hemoglobin affinity for oxygen. Once hemostasis has been achieved, a more restrictive transfusion strategy (i.e., transfusion if hemoglobin <7 g/dL) is indicated for the majority of patients without severe cardiovascular disease (see section on Trauma/Perioperative Patients).

Clotting factors and platelets are also lost in hemorrhage. The resulting bleeding problems may be aggravated by the dilutional effect of fluid resuscitation on clotting factor activity. Fresh-frozen plasma that contains necessary clotting factors and platelets are needed in massive blood loss to restore adequate coagulation. On the other hand, trauma patients are at increased risk for deep vein thrombosis and pulmonary embolism caused by multiple factors, including vessel damage, abnormal blood flow patterns, and the hypercoagulable state associated with injury. Therefore, some form of venous thromboembolism prophylaxis usually is indicated in multiple-trauma patients or patients with severe single-system injuries (e.g., spinal cord damage) once hemostasis of major injury-related bleeding has been achieved.

The pathophysiology becomes more complicated if the severity of shock is sufficient to require patient admission to the intensive care unit (ICU) after initial resuscitation or surgery. Most patients admitted to the ICU have SIRS, which is the body’s response to injury. This syndrome is defined by a number of hypermetabolic changes reflected in the patient’s temperature, white blood cell count and differential, and respiratory and heart rates. The stress response involves complex interactions between the nervous system and immunomodulating substances and has similar (if not the same) harmful and helpful consequences described with reperfusion following shock. If the underlying problems are left untreated, the patient with SIRS may develop multiple-organ dysfunction syndrome (MODS) during the final stages of illness.

### CLINICAL PRESENTATION

5 The initial presentation of patients with suspected volume depletion can vary markedly, depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion (see Clinical Presentation box). Intravascular depletion as a consequence of blood loss is signified by postural vital sign changes (i.e., changes in pulse and blood pressure between supine, sitting, and standing measurements), and such measurements should be performed unless the diagnosis is obvious, as in the case of bleeding associated with trauma. Early signs and symptoms of dehydration and intravascular depletion caused by gastrointestinal or urinary losses often are relatively nonspecific. Plasma volume losses of <10 mL/kg of body weight usually are associated with minor signs and symptoms of distress. Larger losses are not likely to be well tolerated (Table 31–2), particularly in patients older than 65 years. An 18-year-old athlete and a 65-year-old sedentary individual are likely to have much different responses to a similar amount of fluid loss. The young patient may lose one fourth of his or her circulating blood volume with minimal changes in arterial blood pressure and a relatively low heart rate. However, the elderly patient may have orthostatic changes in blood pressure that are not well tolerated by organs such as the kidneys. Unfortunately, this same elderly patient may not have common signs and symptoms of volume depletion, such as skin turgor changes or thirst, but instead may have more subtle changes (e.g., mental status alterations).

### CLINICAL PRESENTATION OF HYPOVOLEMIC SHOCK

#### General

- The initial presentation of adult patients with suspected volume depletion could vary markedly, depending on factors such as age, concomitant disease states and medications, and the etiology and rapidity of depletion.
- Plasma volume losses of <10 mL/kg of body weight usually are associated with minor signs and symptoms of distress.

#### Symptoms

- Patients may present with thirst, nausea, anxiety, weakness, light-headedness, and dizziness.
- Patients may report scanty urine output and dark-yellow urine.

#### Signs

- With more severe volume loss:
  - Patients would have marked increases in heart rate (e.g., >120 beats/min) and respiratory rate (e.g., >30 breaths/min).
  - Blood pressure would be decreased (e.g., systolic blood pressure <90 mm Hg).
  - Mental status changes or unconsciousness may occur.
  - Agitation may be present if the patient is conscious.
  - Body temperature would be low or normal [e.g., 36°–37°C (96.8°–98.6°F)] in the absence of concomitant infection with cold extremities and decreased capillary refill on physical examination.
The diagnosis of dehydration and intravascular depletion in children is complicated by difficulties in obtaining an accurate history. However, some excellent resources are available for healthcare providers, such as the Centers for Disease Control and Prevention (CDC) guidelines (www.cdc.gov), which discuss the evaluation and management of diarrhea in patients of all ages. In younger children, parental observations are important for estimating fluid deficits and monitoring the management of diarrhea in patients of all ages. In younger children, parental observations are important for estimating fluid deficits and deciding whether hospitalization is necessary. Fortunately, prospective data suggest that parental histories are predictive of acidosis and the need for hospitalization. Regardless of patient age or preexisting conditions, the initial monitoring of a patient with suspected volume depletion should include the following noninvasive parameters: vital signs, urine output, mental status, and physical examination (Fig. 31–3).

Although the presenting signs and symptoms of circulatory insufficiency are variable, patients usually have decreased blood pressure, increased heart and respiratory rates, and a normal or low-normal temperature (e.g., 36°–37°C [96.8°–98.6°F]) in the absence of infection, exposure to extremes of temperature, and medications that impair thermoregulation. As mentioned earlier, recordings of vital signs must be interpreted in light of known or suspected baseline conditions. For example, alcohol, β-blockers, butyrophenones such as haloperidol, diuretics, and medications with anticholinergic effects may impair thermoregulation. Medications such as β-blockers and calcium channel blockers may alter resting blood pressure and heart rate, as well as the subsequent response to therapeutic interventions.

Although a blood pressure reading of 110/70 mm Hg (systolic/diastolic) may be acceptable in many patients, it may be inadequate in a patient with preexisting hypertension who normally has a blood pressure of 170/105 mm Hg. At the other extreme, patients with very low blood pressure may have inaudible or inaccurate determinations with cuff (sphygmomanometric) measurements. Chapter 19 details blood pressure measurement (e.g., cuff size, position). In this case, intraarterial monitoring is indicated. As a noninvasive tool, the respiratory rate may correlate better than the heart rate with volume loss, but respiratory rate often is not used. The respiratory rate may be elevated because of anxiety or as a compensatory mechanism for the metabolic acidosis caused by lactic acidosis associated with poor tissue perfusion.

Although the kidneys continually produce urine, the bladder stores the urine for intermittent elimination. For the initial diagnosis and management of acute circulatory insufficiency, a catheter can be inserted into the bladder for measuring urine output. In contrast to thirst, which is a relatively insensitive indicator of volume depletion, urine output is generally diminished with inadequate fluid administration and increases with appropriate resuscitation. This presumes, of course, that acute renal failure or medications such as diuretics are not altering the expected response. Adults should produce at least 0.5 to 1 mL/kg/h of urine, whereas children under 12 years of age should produce at least 1 mL/kg/h (2 mL/kg/h if younger than 1 year).

Mental status changes associated with volume depletion, if present, may range from subtle fluctuations in mood to unconsciousness. Although the latter finding typically is indicative of more severe depletion, less dramatic findings should not be interpreted as indicating mild fluid deficits. Losses of 4 L of plasma volume may be associated only with lassitude in an otherwise healthy adult patient. Similar interpretation difficulties must be considered when performing the initial physical examination. An orderly progression

<sup>a</sup>Patients may have intermediate degrees of volume loss in addition to those listed, but the amount of loss often is difficult to quantify. The presentations may also vary greatly in patients with similar amounts of loss (young athlete vs sedentary, elderly person). In patients particularly prone to complications associated with fluid overload, the fluid can be administered in multiple smaller boluses titrated to clinical response. See text for a more in-depth discussion of some of the guidelines in this table.
Cardiovascular Disorders

from warm, reddish skin with appropriate capillary refill (rapid return of blood flow to the extremity after removal of compression) to cold, cyanotic discoloration with impaired refill may not occur. Also, dry mucus membranes in elderly patients may be caused by mouth breathing or medications and not by fluid depletion.

**TREATMENT**

**Hypovolemic Shock**

**DESIRED OUTCOME**

The desired outcomes of therapy for patients with hypovolemic shock are to prevent further progression of the disease with subsequent organ damage and, to the extent possible, to reverse organ dysfunction that has already taken place.

**GENERAL APPROACH TO TREATMENT**

Milder forms of volume depletion may be managed in outpatient settings. For example, supplemental fluids can be added to the usual estimated daily requirements of 30 to 35 mL/kg in patients older than 12 years with dehydration. Commercially available carbohydrate/electrolyte drinks generally are more palatable than water and may promote earlier recovery. The rationale for combining carbohydrates with sodium is based on the cotransport absorption mechanism in the intestinal tract. With diarrheal states in particular, sodium absorption is impaired. Because water follows sodium, the diarrhea is likely to continue despite oral crystallloid fluid administration until the intestinal pathology resolves. However, when dextrose and sodium are combined in a 1:1 equimolar amounts, both are absorbed via the cotransport mechanism, which also allows for absorption of water. This concept forms the basis for the World Health Organization’s (WHO) oral rehydration solution, which contains 75 mmol/L of dextrose, 75 mmol/L of sodium, 20 mmol/L of potassium, 65 mmol/L of chloride, and 10 mmol/L of citrate for a total osmolarity of approximately 250 mOsm/L.3 Commercially available over-the-counter rehydration drinks for children in the United States also have an osmolality of approximately 250 mOsm/L but typically contain 50 mmol/L or less of sodium, and the dextrose-to-sodium ratio often is 3:1. How these differences between commercially available formulations and the WHO rehydration formula might affect hospitalization rates is unclear, but ad hoc attempts to alter the commercially available products to make them more consistent with the WHO formula are not recommended.3 Improper home mixing of a previous WHO formulation led to cases of hypernatremia.5 Outpatient rehydration of children usually is recommended for those with uncomplicated (e.g., vomiting less than 48 hours) acute gastroenteritis and relatively mild dehydration after the exclusion of more severe illnesses such as bowel obstruction. The need for intravenous (IV) rehydration often is overestimated. Randomized studies conducted in pediatric emergency departments have found oral rehydration to be at least as effective as IV rehydration.10 In one study, children receiving oral rehydration for acute gastroenteritis had shorter lengths of stay than those receiving IV rehydration (225 vs 358 minutes; P < 0.01). Furthermore, there was a trend toward decreased hospital admissions in the oral compared with the IV rehydration group (11% vs 25%; P = 0.2).11

Hospitalization is indicated for more severe forms of circulatory insufficiency. If access to the circulatory system for administration of fluids and medication was not obtained prior to hospitalization, this should be a priority. Venous access generally is obtained during the preliminary examination process that includes the ABCs of life support (i.e., airway, breathing, and circulation), assessment of vital signs and mental status, and determination of urine output after catheterization. Whenever large-volume fluid resuscitation is expected, as in hemorrhagic shock, at least two IV catheters are desirable. Because flow is a function of tubing length and catheter diameter, large-bore peripheral IV lines are preferred over longer central lines. Unfortunately, vascular access in some patients may be problematic, and other routes (e.g., intravenous infusion in children) may be necessary. One interesting method of fluid administration that has been investigated in elderly patients is subcutaneous infusion, or hypodermoclysis. With hypodermoclysis, common dextrose and sodium-containing fluids typically given by the intravenous route are given by subcutaneous infusion at sites such as the upper arm, chest, abdomen, or thigh, depending on factors such as patient or provider preference. Hyaluronidase has been used as a spreading agent to facilitate fluid absorption by this route, but its benefit versus risk profile has yet to be clearly elucidated; in particular, allergic reactions with this agent have been a concern, although a recombinant form is now available that has the potential for fewer reactions compared to the older bovine-derived products. Hypodermoclysis is not used commonly in the United States, probably because of concerns of adverse effects that were found in early studies that used excessively hypotonic or hypertonic solutions, as well as issues related to reimbursement when considered in ambulatory, home, or palliative care settings. Although relatively high fluid administration rates have been achieved in some studies involving hypodermoclysis, this method of infusion should not be used in patients with more severe forms of dehydration or hypovolemia until additional supportive information from clinical trials is available. Although alternative methods of fluid administration, such as hypodermoclysis, are desirable, well-conducted trials are needed before such methods can be recommended for routine use.

**PHARMACOLOGIC THERAPY**

Dextrose-in-water solutions may be appropriate for uncomplicated dehydration caused by water deprivation, but crystalloid (sodium-containing) solutions should be used for forms of circulatory insufficiency that are associated with hemodynamic instability. In the latter situation, IV solutions with sodium concentrations approximating normal serum sodium values usually are indicated because they cause more expansion of the intravascular and interstitial spaces compared with dextrose solutions. Lactated Ringer’s and normal saline solutions are examples of such crystalloid solutions that frequently need to be administered in large volumes when given to patients with more severe forms of hypovolemia. A “large” amount of fluid does not mean a single bolus volume typically used as fluid challenge in a critically ill patient. An isolated bolus (e.g., 250–500 mL) in a young adult trauma patient is unlikely to cause a substantial change in blood pressure or acid–base balance. Therefore, multiple fluid boluses usually are often needed in such patients to achieve hemodynamic stability in the perioperative period. On the other hand, overly aggressive fluid administration should be avoided, especially in patients with heart failure or impending pulmonary edema. In a randomized trial involving patients with acute lung injury and radiographic presence of pulmonary edema, a more conservative fluid management strategy led to significantly fewer ventilator-free days and days not spent in an ICU (P < 0.001).13

The choice between normal saline and lactated Ringer’s solutions for hypovolemia is largely based on clinician preference. Traditionally, lactated Ringer’s solution has been recommended for patients with hemorrhage because it is unlikely to cause the hyperchloremic metabolic acidosis that is seen with infusions of large volumes of normal saline. More recently, concerns have been raised relative to the proinflammatory effects (e.g., neutrophil

*Based on administration of 1 L of each solution for comparative purposes only. This amount of fluid, particularly for 3% saline and 25% albumin, would be inappropriate and likely harmful if given over a short period of time. Numbers are approximations; arrows indicate direction of fluid shift and plus signs indicate fluid pulled from other compartments.

*After distribution and attainment of steady-state conditions, 60% of albumin (and associated fluid) is in interstitial compartment and 40% is in intravascular compartment.

Although lactated Ringer’s solution does contain lactate, it does not cause substantial elevations in circulating lactate concentrations when used as a resuscitation solution.13 Once adequate plasma volume has been restored by fluid administration, the body can readily clear the blood of the excess lactate that has accumulated from both anaerobic metabolism and from lactated Ringer’s solution. However, blood samples for lactate determinations drawn through catheters (arterial and venous) that have not been cleared appropriately may have spurious increases or decreases in lactate concentrations because of retained lactated Ringer’s and nonlactated solutions (e.g., varying concentrations of dextrose-in-water or sodium chloride), respectively.14 Therefore, blood samples for lactate concentration determinations should be drawn from a catheter that has been cleared adequately (e.g., 5 mL) of infusate after temporarily stopping the fluid infusion.

A number of pharmacologic therapies show promise in animal models of shock, but few demonstrate success in subsequent trials involving patients with shock. In large part this is a result of the lack of acceptable animal models of shock that mimic the pathophysiology of patients.15 In cases in which a relevant animal model is available, care must be taken when extrapolating the information to forms of shock other than the one under study. This may be the problem with naloxone, which has been shown to raise blood pressure in some studies of shock but not in others. While research continues on medications or fluids that improve oxygen transport, optimize oxygen utilization, reduce reactive oxygen species and reperfusion injuries, fluids remain the mainstay of therapy, although their use is not devoid of controversy.

Larger-molecular-weight solutions (i.e., >30,000) known as colloids have been recommended in conjunction with or as replacements for crystalloid solutions. Examples of colloids used as plasma expanders in the United States include albumin, hydroxyethyl starch, and dextran. Albumin is known as a monodisperse colloid because all its molecules are of the same molecular size and weight (~67,000), whereas hydroxyethyl starch and dextran solutions are polydisperse compounds with molecules of varying molecular size that are roughly proportional to molecular weight [weight averaged molecular weights of 600,000 (range 450,000–800,000) for 6% hetastarch in normal saline 450/0.75, 670,000 (range 450,000–800,000) for 6% hetastarch in lactated electrolyte 670/0.75, 130,000 (range 110,000–150,000) for 6% tetrastarch in normal saline 130/0.4, 40,000 (range 10,000–90,000) for dextran 40, or 70,000 to 75,000 (range 20,000–200,000) for dextran 70 or dextran 75, respectively]. In light of these differences, colloid comparisons are based on weight-averaged [(number of molecules at each weight × particle weight)/total weight of all molecules] or number-averaged (arithmetic mean of all particles’ weights) molecular weight.16 The size and weight differences of the colloids have important implications for the distribution of the products because lower-molecular-weight substances are retained in the intravascular space for a shorter period of time as a result of more rapid leakage across the vessel membrane. The theoretical benefit common to all colloids is based on their increased molecular weight (average molecular weight in the case of hydroxyethyl starch and dextran) that corresponds to increased intravascular retention time in the absence of increased capillary permeability compared with crystalloids. Even in patients with intact capillary permeability, the colloid molecules eventually will leak through the membrane. In the case of albumin with a distribution half-life of 15 hours in normal subjects, approximately 60% of administered albumin molecules (and associated fluid) would be shifted to the interstitial space within 3 to 5 days of exogenous administration. In patients with altered permeability (e.g., acute respiratory distress syndrome), the leakage of albumin from the intravascular to the

interstitial space may occur within hours, not days. The primary adverse effect concern of all colloids is fluid overload, which is an extension of their pharmacological action. Another adverse effect of increasing concern is renal dysfunction that seems to be related to hyperoncotic (e.g., 25% albumin and other starch and dextran products. The mechanism of this adverse effect may be related to alteration of normal glomerular oncotic pressure differences or formation of lesions in the kidney.  

Albumin is available in 5% and 25% concentrations. Plasma protein fraction has oncotic actions similar to a 5% albumin solution, which is not surprising because albumin is the predominant protein in this product. When given in equipotent amounts, albumin is much more costly than crystalloid solutions. Additionally, the 5% and 25% albumin solutions typically are priced such that no cost savings is associated with dilution of the 25% product to make a 5% concentration. In general, dilution should be avoided because of the possibility of preparation errors; cases of hemolysis and death have occurred when 25% albumin was inappropriately diluted with sterile water for injection, causing a dramatic lowering of effective concentration. In general, the 5% albumin solution is used for hypovolemic states. The 25% solution should not be used for acute circulatory insufficiency unless it is used in combination with other fluids or it is being used in patients with excess total body water but intravascular depletion as a means of pulling fluid into the intravascular space. An example of the latter condition is cirrhosis with ascites in which total body water is substantially increased, but the patient is hypotensive as a consequence of lack of intravascular volume. To justify this use of hyperoncotic albumin from a cost-effectiveness standpoint presumes that there is evidence of adverse effects associated with the excess water (e.g., interstitial fluid accumulation in the lungs) and that the albumin remains in the intravascular space long enough to be of benefit. Albumin has a variety of functions beyond plasma expansion, such as binding properties, inflammatory gene modification, and antioxidant and free radical scavenging effects, which have been used to justify its administration instead of less expensive crystalloid or other colloidal products. Although appealing theoretically, improved patient outcomes related to these properties have not been documented in adequately powered, randomized, controlled trials. Additionally, the clinician must realize that the properties of commercially available albumin products are not biologically identical to those of native albumin. For example, denaturation of the products may lead to inefficient binding and decreased oncotic activity.

Hydroxyethyl starch products have been developed as synthetic alternatives to albumin that is derived through the fractionation of donated human blood. The various products are differentiated by two numbers, one for the average mean molecular weight and one for the degree of hydroxyethyl substitution of glucose. For example, hetastarch is expressed as 450/0.7 based on weight and substitution, respectively. Most of the trials comparing albumin with hydroxyethyl starch products for volume expansion have found no significant differences in clinically important outcomes (e.g., mortality). Few trials have directly compared hydroxyethyl starch products with crystalloid solutions for intravascular expansion. Although hydroxyethyl starch products often are stated as being contraindicated in bleeding disorders, they have been most studied in patients with blood loss (e.g., trauma and perioperative patients). Hydroxyethyl starch should be avoided in situations where short-term impairments in hemostasis could have dire consequences, such as in patients undergoing cardiopulmonary bypass surgery and patients with intracranial bleeding. Hydroxyethyl starch may aggravate bleeding through mechanisms specific to this colloid (e.g., decreased factor VIII/von Willebrand factor). These mechanisms have not been well elucidated and often are difficult to distinguish from the dilutional effects on clotting factors caused by all plasma expanders; however, the risk of coagulopathy appears to be related to increasing starch substitution (greater than 0.4), and increasing doses and durations of administration. Renal dysfunction associated with hydroxyethyl starch products may also be a function of starch substitution and high doses. In a study comparing a pentastarch (200/0.5) to a crystalloid solution for severe sepsis, the cumulative dose of the starch product was associated with an increased need for renal replacement therapy ($P < 0.001$) and a higher 90-day mortality ($P = 0.001$). Hydroxyethyl starch may cause elevations in serum amylose concentrations but does not cause pancreatitis.

Dextran 40, dextran 70, and dextran 75 are available for use as plasma expanders in the United States. The numbers refer to the average molecular weight of the solutions. In general, dextran solutions are not used as often as albumin or hydroxyethyl starch products for plasma expansion, possibly because of concerns related to aggravation of bleeding (i.e., anticoagulant actions related to inhibiting stasis of microcirculation) and anaphylaxis that is more likely to occur with the higher-molecular-weight solutions. However, both of these concerns can be reduced if proper attention is paid to patient selection and, in the case of bleeding, published dosing guidelines with regard to the amounts of these products that should be infused. There are few comparative trials involving the dextran solutions, but the intravascular expansion within hours after infusion is approximately equal to the amount of dextran infused.

The crystalloid versus colloid debate was intensified when a meta-analysis by the well-respected Cochrane group found an overall increase in mortality associated with albumin using pooled results of randomized investigations. The meta-analysis involved 30 randomized trials with 1,419 patients (relative risk of death with albumin vs no administration or crystalloid administration, 1.68; 95% confidence interval [CI], 1.26–2.23). For hypovolemia (caused by blood loss in the majority of studies), the risk of death associated with albumin administration was not quite statistically significant (relative risk, 1.46; 95% CI, 0.97–2.22). With the notable exception of trauma patients, a subsequent and more comprehensive systematic review did not find increased mortality attributable to albumin. Furthermore, a landmark investigation involving almost 7,000 critically ill patients (conducted after the previously mentioned meta-analyses) did not find statistically significant differences in 28-day mortality between patients resuscitated with either normal saline or 4% albumin. As in the previous meta-analysis, there was a trend toward increased mortality in patients with trauma, which became statistically significant ($P = 0.003$) when analyzed at 24 months in a subset of patients with traumatic brain injury. This multicenter, randomized, double-blind investigation, referred to as the Saline versus Albumin Fluid Evaluation (SAFE) study, involved a heterogeneous group of ICU patients and was not sufficiently powered to look at various subsets, so clinicians must be cautious when extrapolating the results to more specific patient populations. With this caution in mind, this trial provides strong evidence that crystalloid solutions should be considered first-line therapy in patients with hypovolemic shock, particularly in the United States where cost differences between crystalloids and colloids are substantial.

### SPECIAL POPULATIONS

#### Trauma/Perioperative Patients

The need for immediate treatment of hemorrhagic circulatory insufficiency with plasma expanders (i.e., crystalloids or colloids) seems obvious, but no large, well-controlled trials conducted in
humans have supported this practice. To the contrary, evidence suggests that fluid resuscitation beyond minimal levels (i.e., mean arterial pressure >40–60 mm Hg) is harmful in patients with penetrating abdominal trauma due to hemodilution and clot destabilization. One prospective study involving 598 adult patients with gunshot or stab wound injuries to the torso and systolic blood pressure measurements of 90 mm Hg or less found that delayed fluid resuscitation until operation was associated with increased survival and discharge from the hospital (P = 0.04). Since concerns were expressed about the comparability of the immediate and delayed resuscitation groups, particularly because true randomization did not take place, a follow-up randomized trial was conducted to verify the findings. There were no differences in survival (four deaths in each group) in the second trial regardless of whether systolic blood pressure was maintained at >100 mm Hg or to 70 mm Hg. Both studies were conducted in populated urban areas with approximately 2 hours from the time of injury to operation. Therefore, the results may not be applicable to rural areas with extended transport times. There also is a concern in applying the results of these investigations to patients with certain kinds of single-system injuries, particularly head trauma, where cerebral perfusion pressure is of primary importance. Although the applicability of these studies to other populations and settings is debatable, the presumption of benefits from immediate plasma expansion in all preoperative patients with circulatory insufficiency caused by hemorrhage is no longer valid. Instead, the initial priority should be surgical control of the bleeding source; until this is possible, fluids should be given in small aliquots to yield a palpable pulse and to maintain mean pressures no more than 60 mm Hg and systolic pressures no more than 90 mm Hg based on accurate measurements (e.g., arterial monitoring).

### CLINICAL CONTROVERSY

Some clinicians believe that hypertonic solutions should be used to lower intracranial pressure in patients with head injuries.

By causing redistribution (i.e., pulling fluid) from the intracellular space, hypertonic solutions cause rapid expansion of the intravascular compartment, which is essential for vital organ perfusion. In head-injured patients, it has been postulated that this redistribution should decrease intracranial pressure because the vessels of the brain are more impermeable to sodium ions than are vessels in other areas of the body. Additionally, hypertonic saline solutions have beneficial immunomodulating actions when compared with more isotonic solutions in experiments with animals, although these actions have not always translated into similar beneficial effects in patients.

Potential dosing and administration errors and related adverse events can occur when hypertonic saline is ordered and administered by clinicians relatively unfamiliar with its use. Potential adverse events include cellular crenation and damage caused by the dramatic fluid shifts associated with hypernatremia, hyperchloremic metabolic acidosis from hyperchloremia, and peripheral vein destruction from high osmolality. In the limited number of studies conducted in humans to date, such adverse events have been uncommon and apparently of little clinical importance.

Unfortunately, beneficial outcome data attributable to administration of these hypertonic solutions are lacking. Most of these studies were conducted in prehospital and emergency department settings using 250 mL of 7.5% sodium chloride with or without 6% dextran 70. A meta-analysis of randomized, controlled trials found no statistical difference between the survival rates of patients receiving the hypertonic saline solutions and those receiving standard isotonic crystalloid solutions. Additionally, a subsequent double-blind, randomized controlled trial involving 229 patients with hypotension and severe brain injury demonstrated no significant differences in neurologic function at 6 months when 250 mL of 7.5% saline or lactated Ringer’s solution was administered as part of a prehospital resuscitation regimen. Part of the explanation for this finding may be related to supplemental crystalloid fluids that were given routinely to patients in both the treatment and control groups, which probably would increase the number of patients needed to demonstrate a statistically significant difference in mortality. It is interesting to note that the hypertonic saline solutions in such prehospital trials appear to have been administered by peripheral veins, despite their very high osmolality. This is deserving of further investigation since intravenous solutions with osmolality values above 600 to 1,200 mOsm/kg (the high end for some peripheral parenteral nutrition solutions) are usually administered through central catheters. For example, the osmolality of 3% sodium chloride is 1,026 mOsm/kg and it is typically recommended for central line administration.

In order to address ongoing questions of efficacy, the National Heart, Lung, and Blood Institute evaluated hypertonic saline for trauma patients with shock and severe traumatic brain injury. These two trials were conducted by a network of sites known as the Resuscitation Outcomes Consortium (ROC). The parallel trials were both stopped when it was determined that hypertonic saline was no better than normal saline and further enrollment would not change the 33 outcomes. Therefore, normal saline is the fluid of choice when a hypertonic solution is desirable because it contains 154 mmol/L of both sodium and chloride. Given their relatively poor intravascular expansion and association with poor outcome in animal models of closed head injury, hypertonic solutions should be avoided in this population.

In addition to crystalloid solutions, colloids have been used for plasma expansion in patients with perioperative circulatory insufficiency. In the United States, albumin and starch (i.e., hydroxyethyl starch) derivatives are used most commonly, although dextran solutions also are available commercially. The major theoretical advantage of these compounds is their prolonged intravascular retention time compared with crystalloid solutions. In contrast to isotonic crystalloid solutions that have substantial interstitial distribution within minutes of IV administration, colloids remain in the intravascular space for hours or days, depending on factors such as capillary permeability.

The colloids, particularly albumin, are expensive solutions. Therefore, it is difficult to justify the additional cost of colloidal products unless the benefit-to-risk ratio is substantially greater than that associated with inexpensive crystalloid solutions. This does not appear to be the case based on randomized, controlled studies and meta-analyses comparing colloid and crystalloid solutions for acute circulatory insufficiency. Because other colloids, such as hydroxyethyl starch, almost always have been compared with albumin and not with crystalloid solutions in published clinical studies (with no clinically important differences found), there is no reason to suspect that these other colloids have any unique advantages as volume expanders. Adverse effects associated with colloids appear to be

The preceding discussion dealt primarily with acute circulatory insufficiency, but there are other considerations with regard to fluid replacement in elective surgical procedures. Preoperative fluid deficits in patients undergoing minor procedures may be associated with increased perioperative morbidity, some of which (e.g., drowsiness, dizziness) may be reduced by appropriate fluid administration prior to surgery. However, care must be taken to avoid overhydration in the perioperative period because excess fluid will lead to weight gain and decreased pulmonary function. Some evidence suggests that fluid restriction on the day of surgery may reduce postoperative morbidity in patients undergoing major surgical procedures. In one randomized, multicenter trial, use of a restricted intraoperative and postoperative IV fluid protocol led to significantly fewer cardiopulmonary (7% vs 24%; P = 0.007) and wound (16% vs 31%; P = 0.04) complications. As the preceding discussion indicates, the benefits and risks of fluid administration in the perioperative period are not just a function of too little or too much fluid but involve other patient- and procedure-related issues.

Another consideration in the patient with penetrating injuries or surgery is the potential need for blood product administration (Table 31–6) to replace oxygen-carrying and clotting functions. Although a small group of trauma patients respond to the initial fluid bolus and remain stable, most patients respond initially and then deteriorate. The latter patients, as well as patients undergoing blood loss associated with surgery, frequently need blood components such as packed red blood cells. In the case of the latter component, red blood cells contain hemoglobin that delivers oxygen to tissues. Neither crystalloids nor colloids perform this function.

Administration of excessive blood products may be counterproductive. In the case of red blood cells, attempts to raise the hematocrit to high-normal or supranormal concentrations may decrease oxygen delivery by increasing blood viscosity. Additionally, there are immunomodulatory concerns with red blood cell administration. Although there is no optimal hematocrit value for all patients, a minimum hematocrit concentration of 30% (equivalent to a hemoglobin concentration of 10 gm/dL) traditionally has been used as the threshold for transfusion, particularly in patients at risk for ischemia, such as those with CAD. Use of a more liberal transfusion strategy has been curtailed in many institutions with the publication of a randomized, multicenter trial involving critically ill patients that found 30-day mortality to be similar whether patients were transfused at a hemoglobin concentration less than 7 or 10 g/dL (18.7% vs 23.3%, respectively; P = 0.11). The mortality during hospitalization was significantly lower in the restrictive group (22.2% vs 28.1%; P = 0.05). Although the investigators were cautious about extrapolating the results of this investigation to patients with myocardial ischemia, the study does question the use of a liberal transfusion strategy for critically ill patients.

Blood products have risks beyond immunomodulation. There is the rare but important risk of virus transmission [e.g., human immunodeficiency virus (HIV), hepatitis]. Citrate that is added to stored blood to prevent coagulation may bind to calcium, resulting in hypocalcemia, although potassium and phosphate concentrations often are elevated in stored blood, particularly when hemolysis has occurred during storage. In patients receiving large amounts of blood, prophylactic calcium administration may be warranted until levels are available. Other issues that must be considered with blood product administration include monitoring for transfusion-related reactions and attention to appropriate warming, particularly when large volumes are given to pediatric patients, because hypothermia is associated with increased fluid requirements and mortality.

Since its commercial release in the United States, recombinant factor VIIa has been used for a variety of off-label uses related to trauma and bleeding. For example, in patients with massive blood loss a cocktail of cryoprecipitate, platelets, and recombinant factor...
VIIa has been suggested to rapidly attain hemostasis.18 These more severe forms of blood loss are not only a function of the type of injury but also factors such as medications (e.g., aspirin, coumadin, clopidogrel, enoxaparin) and disease states that impair normal coagulation. Large well-controlled trials are needed to define the role of recombinant factor VIIa in clinical practice given its high cost and potential thromboembolic complications. There are specific concerns with its use in trauma patients related to subpopulations most likely to see benefit since there are issues related to appropriate dose, timing, and diminished effectiveness in patients with acidosis and severe hypothermia. A large randomized controlled trial involving patients with penetrating and blunt trauma is currently underway that should help to resolve many of these concerns.39

The periodic shortages, high costs, and adverse effect concerns related to blood products have prompted investigations of alternative “bloodless” strategies. In addition to the use of more restrictive transfusion thresholds, as mentioned previously, these strategies have included hemoglobin-based oxygen carriers and perfluoro-carbon compounds to deliver oxygen to tissues. Other strategies have aimed at reducing blood loss through the use of improved procedural and surgical techniques, as well as the administration of hemostatic medications.

Patients with Thermal Injuries

There are a number of formulas for estimating fluid requirements in thermally injured patients, but there is little reason to choose one over another based on well-controlled studies. In general, the amount of loss corresponds to the size of the thermal injury. Guidelines recommend approximately 2 to 4 mL/kg of isotonic fluid (lactated Ringer’s solution) for each percent burn can be used for calculating the expected fluid requirements for the first 24 hours after the burn.40 For example, a 60-kg person with 30% body surface area (BSA) burns is expected to require 5,400 to 7,200 mL of fluid over the initial 24 hours. Regardless of the calculated deficit, fluids should be administered until adequate tissue perfusion has been documented (e.g., maintenance of urine output of 0.5–1 mL/kg in adults) or adverse effects (e.g., pulmonary edema) occur. Crystalloids are preferred as initial therapy for burn victims because there is no substantial evidence that colloids mobilize edematous fluid, and there is a theoretical concern that extravascular fluid accumulation might be prolonged by the oncotic actions of albumin and other colloid products that have leaked through vessel walls.41 Additionally, there is no evidence that colloids reduce mortality in patients with thermal injuries. Some novel therapies for thermal resuscitation have been studied, although larger confirmatory trials are needed prior to use apart from research protocols. For example, in a prospective study involving patients with >30% BSA burns, antioxidant therapy with extremely high doses on IV vitamin C (66 mg/kg/h for 24 hours) reduced resuscitation fluid requirements and wound edema.42 The proposed mechanism is reduction in free radical–induced increases in capillary permeability.

The appropriate use of invasive hemodynamic monitoring tools, such as right-sided heart catheterization in patients with hypovolemic shock, is controversial.

■ ONGOING MONITORING

One form of monitoring that may take place in the emergency and operating rooms, as well as in the ICU, requires placement of a central venous pressure (CVP) line. Monitoring of CVP provides

the clinician with a somewhat insensitive yet useful estimate of the relationship between increased right atrial pressure and cardiac output. A protocol that used a particular type of central catheter to perform continuous monitoring of central venous oxygen saturation in conjunction with so-called goal-directed therapy in the first 6 hours of patient arrival in an urban emergency department resulted in decreased mortality compared with standard monitoring (30.5% vs 46.5%; P = 0.009).43 However, the patients in this study had severe sepsis and septic shock, so the results might not be applicable to other forms of shock with different pathophysiologic considerations. For example, in hemorrhagic shock due to trauma, the most important intervention is surgical control of bleeding, and anything that delays this control is likely to increase, not decrease, mortality. Until additional studies have been performed, it would be premature to mandate goal-directed therapy with the associated central venous monitoring in patients with nonseptic forms of shock, particularly shock due to blood loss. In fact, so-called “upstream” measurements of perfusion such as CVP are not a useful guide for fluid management in hospitalized patients,44 and are being replaced by “downstream” markers such as urine output and lactate levels that are more likely to reflect end-organ dysfunction.45 A more complete discussion of invasive and noninvasive hemodynamic monitoring is given in Chapter 30.

A number of laboratory tests are indicated for subacute monitoring of shock in the ICU setting. These include a renal battery for assessing possible electrolyte alterations and kidney perfusion (e.g., BUN and creatinine). Among other things, a complete blood count will enable assessment of possible infection (white blood cell count), oxygen-carrying capacity of the blood (hemoglobin, hematocrit), and ongoing bleeding (hemoglobin, hematocrit, and platelet count). The prothrombin time or international normalized ratio and partial thromboplastin time will give an indication of the ability of the blood to clot because, in the case of hemorrhagic shock, clotting factors are lost and diluted. An increasing lactate concentration (arterial, mixed venous, or central venous), an increasing arterial base deficit, or a decreasing bicarbonate concentration are global markers indicative of inadequate perfusion leading to anaerobic metabolism with accumulation of lactic acid. Although the value of these surrogate markers for improving patient outcomes is more controversial, they are considered traditional end points of resuscitation in certain populations such as trauma patients.46 Other tests may be indicated if organ dysfunction is likely. For example, when blood flow to the liver is interrupted because of sustained hypotension, a condition known as shock liver may occur. In this condition, the levels of transaminases on a liver panel may be markedly elevated in the first couple of days after marked hypotension, although the concentrations should decrease over time.47 Along with laboratory testing, a more extensive history can be obtained during the subacute monitoring period.

The value of pulmonary artery catheters (also known as right-sided heart or Swan-Ganz catheters) has been debated hotly since their introduction. Such catheters are placed to obtain various oxygen-transport variables, some of which cannot be determined reliably from peripheral or other central vessels. The debate was intensified when early studies suggested improved outcomes when cardiac output and other oxygen-transport variables were raised to supranormal levels, the monitoring of which required placement of a pulmonary artery catheter. Subsequent studies using similar monitoring parameters associated with pulmonary artery catheterization gave conflicting results.48

The controversy led to consensus conferences and workshops, the development of organizational guidelines, and the publication of a meta-analysis (which found a statistically significant reduction in morbidity using pulmonary artery catheters to guide therapy).49 Ultimately, a large randomized, controlled trial involving pulmonary artery catheters was conducted in high-risk surgical patients.50
The trial involved 1,994 patients. The mortality was almost identical for the catheter and control groups (7.8% vs 7.7%; 95% CI, 2.3–2.5). There were no episodes of pulmonary embolism in the catheter group and eight episodes in the control group (P = 0.004). This trial is important not only because of the implications for high-risk surgical patients but also because it allows for the conduct of future trials in other patient populations without some of the ethical issues raised about such trials in the past.

Part of the concern regarding pulmonary artery catheterization relates to interpretation of its results by inexperienced practitioners. Studies in Europe and the United States found that one of two physicians incorrectly interpreted a tracing from a pulmonary artery catheter. This could explain some of the results of studies finding no benefits to pulmonary artery catheterization or, in some cases, worse outcomes in the pulmonary artery catheterization group by actions taken as a result of inaccurate measurements or misinterpretation of information obtained from the monitoring process.

Complications related to pulmonary artery catheter insertion, maintenance, and removal include damage to vessels and organs during insertion, arrhythmias, infections, and thromboembolic damage. To avoid the complications associated with pulmonary artery catheterization, other less invasive tools were developed to obtain similar information. For example, cardiac output determinations have been made by Doppler, bioimpedance, dye, and ionic dilution techniques, although such measurements would not provide other data that are obtained routinely with pulmonary artery catheters (e.g., left-sided heart filling pressure). Additionally, advances in pulmonary artery catheter technology that expand the information obtained from such monitoring (e.g., mixed venous oxyhemoglobin) are under investigation. However, given the lack of well-defined outcome data associated with pulmonary artery catheterization, its use is best reserved for complicated cases of shock not responding to conventional fluid and medication therapies.

Commonly measured and calculated hemodynamic and oxygen-transport indices associated with invasive monitoring are primarily global indicators of tissue perfusion. Attempts have been made to find regional and local indicators of hypoperfusion so that circulatory insufficiency could be treated before overt shock occurs. One focus of recent research has been monitoring modalities involving the gastrointestinal tract.

Although the literature is fairly consistent concerning low gastric intramucosal pH (pHi) values being predictive of death, pHi-guided therapy to decrease mortality has not been demonstrated. Additionally, a number of technical considerations remain to be resolved when using pHi or, more recently, capnometry (luminal Pco2, tonometry) for monitoring and therapy. Despite these concerns, measures of regional tissue oxygenation continue to be investigated through a variety of novel monitoring techniques.

In addition to regional monitoring of tissue perfusion, local methods of monitoring are being studied. For example, subcutaneous measurement of tissue oxygen pressure shows promise in preliminary investigations. Regional and local measurements likely will not replace more global indicators of perfusion; rather, the methods will complement each other.

**ONGOING MANAGEMENT**

Proper attention to plasma expansion must be continued into the intraoperative and postoperative periods. A number of neurohormonal changes take place that affect urine output, and patients may have substantial third spacing of fluid depending on the operation and preexisting conditions. Furthermore, postoperative patients are prone to hyponatremia from renal generation of electrolyte-free water and from antidiuretic hormone release. As in acute resuscitation, the administration of hypotonic solutions in the perioperative period does not prevent the decrease in extracellular volume that often occurs. Therefore, although excess fluid administration is to be avoided in the perioperative setting, isotonic crystalloid solutions should be used when fluids are indicated to prevent intravascular depletion and circulatory insufficiency. There is general agreement that the choice of crystalloid solution in the perioperative period should be either normal saline or a lactated Ringer’s (or equivalent) solution. However, there is substantial debate as to which of these two solutions is preferable since comparative studies have involved small numbers of patients.

Of the randomized studies comparing albumin with crystalloid solutions in the perioperative period, the majority found no statistically significant differences between groups. Any significant differences found involved isolated hemodynamic or respiratory variables with no obvious clinical correlates (e.g., duration of mechanical ventilation). Therefore, albumin and other colloids cannot be recommended for the prevention or initial treatment of circulatory insufficiency, although their use may be appropriate in patients who are not responding to crystalloids and are developing problems such as interstitial fluid accumulation. Practice guidelines published by a consortium of academic medical centers reflect this recommendation, but colloids continue to be used widely.

In contrast to many other forms of shock, medications are not indicated in the initial therapy of hypovolemic shock but rather play an adjunctive role in patients who continue to have circulatory insufficiency after fluids have been maximized and volume overload concerns exist. In a multicenter cohort study of blunt-injured patients with hemorrhagic shock, the use of vasopressors within 12 hours of injury was associated with significantly higher mortality at 24 hours (P = 0.001). With hypovolemia, the body’s natural response is to increase cardiac output and to constrict blood vessels to maintain blood pressure. There is no evidence that vasoactive medications improve outcome in patients with hypovolemic shock assuming that fluid therapy is adequate. However, once the cause of acute circulatory insufficiency has been stopped or treated and fluids have been optimized, some patients continue to have signs and symptoms of inadequate tissue perfusion. This may be caused by reperfusion injury. Although the search for a cryptogenic source (e.g., intraabdominal bleeding in a trauma patient) should continue, the clinician may need to administer vasoactive medications to improve perfusion.

Pressor agents such as norepinephrine and high-dose dopamine are to be avoided, if possible, because they may increase blood pressure at the expense of peripheral tissue ischemia. Some sources use stronger language and state that vasopressors are contraindicated in certain forms of shock (e.g., hemorrhagic). This does not help the clinician who is treating a patient with unstable blood pressure despite massive fluid replacement and increasing interstitial fluid accumulation. In such situations, inotropic agents such as dobutamine are preferred if blood pressure is adequate (e.g., systolic blood pressure ≥80–90 mm Hg) because they should not aggravate the existing vasoconstriction. The inotropic agents are justified by presumed inadequate cardiac output for the specific situation, although the measured values may be in the normal range.

When pressure cannot be maintained with inotropic agents or when inotropic agents with vasodilatory properties cannot be used because of inadequate blood pressure concerns, pressors may be required as a last resort. In general, the need for pressors is predictive of the development of MODS and increased length of hospital stay. Although the response to pressor agents may be variable in hypovolemic shock, there does not appear to be resistance as a consequence of altered receptor response, as is sometimes seen in patients with septic shock. Potent vasoconstrictors such as norepinephrine and phenylephrine should be given through central veins because of the possibility of extravasation and necrosis with peripheral administration.
In managing patients with hypovolemic shock, the clinician must be aware of potential adverse effects of medications being used for supportive care purposes. For example, some patients are particularly susceptible to the histamine release associated with morphine and may have substantial decreases in blood pressure. Sodium bicarbonate would seem to be a logical therapy in patients with shock who typically have a metabolic acidosis, but bicarbonate administration has not been shown to improve surrogate hemodynamic markers or patient outcomes and has known disadvantages such as the associated increase in arterial carbon dioxide levels and decrease in serum ionized calcium levels. Propofol is commonly used for sedation in the ICU, but it may cause substantial decreases in blood pressure. The initial dose of propofol probably should be decreased by at least 50% in patients with hemorrhagic shock who have recently been resuscitated and by at least 80% (if it is given at all) in patients who may not be fully resuscitated.

A number of interesting treatments for shock are under investigation, including autotransfusion for removing harmful cytokines from the body. Various alternatives to conventional blood components also are being studied, such as stroma-free hemoglobin and perfluorocarbon compounds, as virus-free alternatives to red blood cell transfusion. Hopefully, these methods will be useful adjuncts to adequate volume replacement, which is the primary therapeutic intervention in managing acute circulatory insufficiency as a result of volume depletion.

### PHARMACOECONOMIC CONSIDERATIONS

The primary therapy for hypovolemic shock is fluid replacement. The institutional cost of 1 L of most crystalloid solutions is less than $1. Assuming that such fluids are used, the associated costs of personnel and equipment then become the primary economic considerations in the resuscitation of patients with hypovolemic shock. However, as mentioned, many clinicians recommend that colloid plasma expanders (e.g., albumin, hydroxyethyl starch, or dextrans) be used to replace some or all of the standard crystalloid solutions. Although the costs of these solutions vary, depending on contractual arrangements, as might occur with purchasing groups, in general, albumin solutions are more expensive than hydroxyethyl starch and dextran products. All these solutions are markedly more costly than crystalloid solutions; in some cases, the differences are 50- to 100-fold, even when used in equipotent amounts.

The only trial that investigated albumin use on a large-scale basis was an observational study involving 15 academic medical centers in the United States. Based on previously published guidelines, 62%

---

**FIGURE 31-4.** Hypovolemia protocol for adults. This protocol is not intended to replace or delay therapies such as surgical intervention or blood products for restoring oxygen-carrying capacity or hemostasis. If available, some measurements can be used in addition to those listed in the algorithm, such as mean arterial pressure or pulmonary artery catheter recordings. The latter can be used to assist in medication choices (e.g., agents with primary pressor effects may be desirable in patients with normal cardiac outputs, whereas dopamine or dobutamine may be indicated in patients with suboptimal cardiac outputs). Lower maximal doses of the medications in this algorithm should be considered when pulmonary artery catheterization is not available. Colloids that can be substituted for albumin are hydroxyethyl starch 6% and dextran 40. See text for an in-depth discussion of these and other issues involved in this protocol. (CHF, congestive heart failure; LR, lactated Ringer’s solution.)
of albumin use was defined as inappropriate, at a cost of $124,939.\(^4\) Presuming equal efficacy and toxicity (as available studies indicate) between crystalloid and colloid solutions, cost-minimization analysis clearly indicates the economic advantages of the crystalloids.

Because medications are not simply alternatives to crystalloids but rather are used when crystalloid therapy has been optimized, there is little reason to compare medication and fluid therapies from an economic perspective. Furthermore, there are no economic comparisons of the various inotropic and vasopressor medications used in the treatment of hypovolemic shock.

**EVALUATION OF THERAPEUTIC OUTCOMES**

**Figure 31–4** is an algorithm that summarizes many of the treatment principles discussed in this chapter. The algorithm is an example of one approach to the adult patient presenting with hypovolemic shock. It presumes that initial rehydration attempts (i.e., outpatient or prehospital) were unsuccessful in restoring circulation. Obviously, modifications may be needed for patient-specific forms of hypovolemic shock. Other limitations of the algorithm should be recognized, particularly the decisions to add or to substitute colloid or medication therapies when crystalloid solutions are not yielding desired results and when to perform pulmonary artery catheterization for more invasive monitoring. Medications become more important for the ongoing management of hypovolemic shock, particularly when the patient is unresponsive to fluids (Fig. 31–5). Medications for more complicated cases of hemorrhagic shock should not detract from the primary effective resuscitative measure—surgical stabilization of bleeding.

**ABBREVIATIONS**

BSA: body surface area
CAD: coronary artery disease

CHAPTER 32

Introduction to Pulmonary Function Testing

JAY I. PETERS AND STEPHANIE M. LEVINE

KEY CONCEPTS

1. Normal ventilation–perfusion ratio. The function of the lungs is to maintain $P_{aO_2}$ and $P_{aCO_2}$ within normal ranges. This goal is accomplished by matching 1 mL mixed venous blood with 1 mL fresh air ($V/Q = 1$). Normally, ventilation ($V$) is less than perfusion ($Q$), and $V/Q$ ratio is 0.8.

2. The air in the lung is divided into four compartments: tidal volume—air exhaled during quiet breathing; inspiratory reserve volume—maximum air inhaled above tidal volume; expiratory reserve volume—maximum air exhaled below tidal volume; and residual volume—air remaining in the lung after maximal exhalation. The sum of all four components is the total lung capacity.

3. Obstructive lung disease is defined as an inability to get air out of the lung. It is identified on spirometry when $FEV_1/FVC$ (force expiratory volume in the first second of expiration/forced vital capacity [total amount of air that can be exhaled during a forced exhalation]) is <70% to 75%.

4. Restrictive lung disease is defined as an inability to get air into the lung and is best defined as a reduction in total lung capacity. It is suspected when FVC is low and $FEV_1/FVC$ is normal.

5. Restrictive lung disease can be produced by a number of defects, such as increased elastic recoil (interstitial lung disease), respiratory muscle weakness (myasthenia gravis), mechanical restrictions (pleural effusion or kyphoscoliosis), and poor effort.

6. The primary function of the respiratory system is to maintain normality of arterial blood gases, that is, arterial pressure of oxygen ($P_{aO_2}$) and arterial pressure of carbon dioxide ($P_{aCO_2}$). To achieve this goal, several processes must be accomplished, including alveolar ventilation, pulmonary perfusion, ventilation—perfusion matching, and gas transfer across the alveolar—capillary membrane. Alveolar ventilation is achieved by the cyclic process of air movement in and out of the lung. During inspiration, the inspiratory muscle contracts and generates negative pressure in the pleural space. This pressure gradient between the mouth and the alveoli draws fresh air (tidal volume) into the lung. Approximately one third of the inspired gas stays in the conducting airways (dead space), and two thirds reaches the alveoli.

CHAPTER 33

Asthma

H. WILLIAM KELLY AND CHRISTINE A. SORKNESS

KEY CONCEPTS

1. Asthma is a disease of increasing prevalence that is a result of genetic predisposition and environmental interactions; it is one of the most common chronic diseases of childhood.

2. Asthma is primarily a chronic inflammatory disease of the airways of the lung for which there is no known cure or primary prevention; the immunohistopathologic features include cell infiltration by neutrophils, eosinophils, T-helper type 2 lymphocytes, mast cells, and epithelial cells.

3. Asthma is characterized by either the intermittent or persistent presence of highly variable degrees of airflow obstruction from airway wall inflammation and bronchial smooth muscle constriction; in some patients, persistent changes in airway structure occur.

4. The inflammatory process in asthma is treated most effectively with corticosteroids, with the inhaled corticosteroids having the greatest efficacy and safety profile for long-term management.

5. Bronchial smooth muscle constriction is prevented or treated most effectively with inhaled β₂-adrenergic receptor agonists.

6. Variability in response to medications requires individualization of therapy within existing evidence-based guidelines for management. This is most evident in patients with severe asthma phenotypes.

7. Ongoing patient education, for a partnership in asthma care, is essential for optimal patient outcomes and includes trigger avoidance and self-management techniques.

Asthma has been known since antiquity, yet it is a disease that still defies precise definition. The word asthma is of Greek origin and means “panting.” More than 2,000 years ago, Hippocrates used the word asthma to describe episodic shortness of breath; however, the first detailed clinical description of the asthmatic patient was made by Aretaeus in the second century. The National Institutes of Health, National Asthma Education and Prevention Program Expert Panel Report 3 (EPR3), has provided the following working definition of asthma:

Asthma is a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role: in particular, mast cells, eosinophils, T-lymphocytes, macrophages, neutrophils, and epithelial cells. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment. The inflammation also causes an associated increase in the existing bronchial hyperresponsiveness (BHR) to a variety of stimuli. Reversibility of airflow limitation may be incomplete in some patients with asthma.

This definition encompasses the important heterogeneity of the clinical presentation of asthma by describing the scientific and clinically accepted characteristics of asthma.

EPIDEMIOLOGY

1. An estimated 22.9 million persons in the United States have asthma (about 7.7% of the population). Asthma is the most common chronic disease among children in the United States, with approximately 6.7 million children affected. The prevalence rate is highest in children 5 to 17 years of age at 10.0%. In the United States, as in other industrialized countries, the prevalence of asthma increased through the 1980s and 1990s but appears to be leveling off. Asthma accounts for 1.6% of all ambulatory care visits (10.6 million physician office visits and 1.2 million hospital outpatient visits) and resulted in 440,000 hospitalizations and 1.7 million emergency department (ED) visits in 2006 (both declined from peaks in the 1990s). Asthma is the third leading cause of preventable hospitalization in the United States; however, hospitalizations have decreased over the past 10 years to 14.9 per 10,000 population with 33% reported in children less than 15 years of age. Asthma accounts for more than 12.8 million missed school days per year. In young children (0–10 years of age), the risk of asthma is greater in boys than in girls, becomes about equal during puberty, and then is greater in women than in men.

Ethnic minorities continue to share the burden of asthma disproportionately. African Americans have a 39% higher prevalence than whites. African Americans are 3 times as likely to be hospitalized and approximately 3 times more likely to die from asthma than whites. In addition, African Americans and Puerto Ricans living in inner cities are four times more likely to experience ED visits than whites. However, Hispanics in general have lower prevalence and hospitalization rates than African Americans or whites.

The estimated direct medical cost of asthma in the United States in 2007 was $14.7 billion. The societal burden of asthma (indirect medical expenditures: loss of productivity and death) in the United States was $5.0 billion. Prescription drugs were the largest

The complete chapter, learning objectives, and other resources can be found at www.pharmacotherapyonline.com.
single direct medical expenditure at $6.2 billion; however, the combined costs of emergency care of acute asthma exacerbations makes up 36% of direct medical costs.1

The natural history of asthma is still not well defined. Although asthma can occur at any time, it is principally a pediatric disease, with most patients being diagnosed by 5 years of age and up to 50% of children having symptoms by 2 years of age.2 Between 30% and 70% of children with asthma will improve markedly or become symptom-free by early adulthood; chronic disease persists in about 30% to 40% of patients, and generally 20% or less develop severe chronic disease.2 Predictors of persistent adult asthma include atopy, onset during school age, and presence of BHR.4 Diminished lung growth may occur in some children (approximately 10%) with asthma.2

In adults, most longitudinal studies have suggested a more rapid rate of decline in lung function in asthmatics than in nonasthmatic normals, primarily reflected in forced expiratory volume in 1 second (FEV1).4 However, the annual decline in FEV1 is less than in smokers or in patients with a diagnosis of emphysema. In general, individuals with less frequent asthma attacks and normal lung function on initial assessment have higher remission rates, whereas smokers have the lowest remission and highest relapse rates.1 The level of BHR tends to predict the rate of decline in FEV1, with a greater decline with high levels of BHR.2 Thus airways obstruction in asthma not only may become irreversible but also may worsen over time owing to airway remodeling (see below).2,4 However, most patients do not die from long-term progression of their disease and their life-span is not different from the general population.4

As with prevalence and morbidity, mortality from acute exacerbations of asthma has been decreasing over the past 10 years, with 3,565 deaths reported in 2007.3 Despite the relatively low number of asthma deaths, 80% to 90% are preventable.2 Most deaths from asthma occur outside the hospital, and death is rare after hospitalization. The most common cause of death from asthma is inadequate assessment of the severity of airways obstruction by the patient or physician and inadequate therapy. The most common cause of death in hospitalized patients is also inadequate or inappropriate therapy. Thus the key to prevention of death from asthma, as advocated by the U.S. National Asthma Education and Prevention Program (NAEPP), is education.2

### ETIOLOGY

1 Epidemiologic studies strongly support the concept of a genetic predisposition plus environmental interaction to the development of asthma, yet the picture remains complex and incomplete.5 Genetic factors account for 60% to 80% of the susceptibility. Asthma represents a complex genetic disorder in that the asthma phenotype is likely a result of polygenic inheritance or different combinations of genes. Initial searches focused on establishing links between atopy (genetically determined state of hypersensitivity to environmental allergens) and asthma, but more recent genome-wide searches have found linkages with genes for metalloproteinases (e.g., ADAM33) and handling bacteria (CHI3L1).5 Although genetic predisposition to atopy is a significant risk factor for developing asthma, not all atopic individuals develop asthma, nor do all patients with asthma exhibit atopy. Disparate phenotypes of asthma (progressive or remodelled versus non-progressive) are likely genetically determined.5

1 Environmental risk factors for the development of asthma include socioeconomic status, family size, exposure to second-hand tobacco smoke in infancy and in utero, allergen exposure, urbanization, respiratory syncytial virus infection, and decreased exposure to common childhood infectious agents.6,7 The “hygiene hypothesis” proposes that genetically susceptible individuals develop allergies and asthma by allowing the allergic immunologic system (Th1 lymphocytes) to develop instead of the system to fight infections (Th2 lymphocytes) and may explain the increase of asthma in developed countries.6,7 The first 2 years of life appear to be most important for the exposures to produce an alteration in the immune response system.4 The hygiene hypothesis is supported by studies demonstrating a lower risk for asthma in children who are exposed to high levels of bacteria or endotoxin, in those with a large number of older siblings, in those with early enrollment into child care, in those with exposure to cats and dogs early in life, or in those with exposure to fewer antibiotics.5,7

Risk factors for early (<3 years of age) recurrent wheezing associated with viral infections include low birth weight, male gender, and parental smoking. However, this early pattern is due to smaller airways, and these risk factors are not necessarily risk factors for asthma in later life.8 Atopy is the predominant risk factor for children to have continued asthma.6,7 Asthma can begin in adults later in life. Occupational asthma in previously healthy individuals emphasizes the effect of environment on the development of asthma.8 The heterogeneity of the asthma phenotype appears most obvious when listing the diverse triggers of bronchospasm (Table 33–1). The various triggers have relative degrees of importance from patient to patient. Environmental exposures are the most important precipitants of severe asthma exacerbations1 (see Table 33–1). Epidemics of severe asthma in cities have followed exposures to high concentrations of Aeroallergens.9 Viral respiratory tract infections remain the single most significant precipitant of severe asthma in children and are an important trigger in adults as well.9 Other possible factors include air pollution, sinusitis, food preservatives, and drugs.

### PATHOPHYSIOLOGY

2 The major characteristics of asthma include a variable degree of airflow obstruction (related to bronchospasm, edema, and mucus hypersecretion), BHR, and airways inflammation (Fig. 33–1). To understand the pathogenetic mechanisms that underlie the many phenotypes of asthma, it is critical to identify factors that initiate, intensify, and modulate the inflammatory response of the airways and to determine how these processes produce the characteristic airway abnormalities.

Inflammation role in this inflammatory process. Inflammatory mediators induce standing of acute inflammation in asthma. Inhaled allergen challenge models contribute most to our understanding of acute inflammation in asthma. Inhaled allergen challenge in allergic patients leads to an early-phase reaction that, in some cases, may be followed by a late-phase reaction. The activation of cells bearing allergen-specific IgE initiates the early-phase reaction. It is characterized by the rapid activation of airway mast cells and macrophages leading to the rapid release of proinflammatory mediators such as histamine, eicosanoids, and reactive oxygen species that induce contraction of airway smooth muscle, mucous secretion, and vasodilatation. The bronchial microcirculation has an essential role in this inflammatory process. Inflammatory mediators induce microvascular leakage with exudation of plasma in the airways. Acute plasma protein leakage induces a thickened, engorged, and edematous airway wall and a consequent narrowing of the airway lumen. Plasma exudation may compromise epithelial integrity, and the presence of plasma in the lumen may reduce mucus clearance. Plasma proteins also may promote the formation of exudative plugs mixed with mucous and inflammatory and epithelial cells. Together these effects contribute to airflow obstruction (Fig. 33–1).

The late-phase inflammatory reaction occurs 6 to 9 hours after allergen provocation and involves the recruitment and activation of eosinophils, CD4+ T cells, basophils, neutrophils, and macrophages. There is selective retention of airway T cells, the expression of adhesion molecules, and the release of selected proinflammatory mediators and cytokines involved in the recruitment and activation of inflammatory cells. The activation of T cells after allergen challenge leads to the release of T-helper cell type 2 (Th2)–like cytokines that may modulate the late-phase response. The release of preformed cytokines by mast cells is the likely initial trigger for the early recruitment of inflammatory cells that then recruit and induce the more persistent involvement by T cells. The enhancement of nonspecific BHR usually can be demonstrated after the late-phase reaction but not after the early-phase reaction following allergen or occupational challenge.

**CHRONIC INFLAMMATION**

Airways inflammation has been demonstrated in all forms of asthma, and an association between the extent of inflammation and the clinical severity of asthma has been demonstrated in selected studies. It is accepted that both central and peripheral airways are inflamed.

In asthma, all cells of the airways are involved and become activated (Fig. 33–2). Included are eosinophils, T cells, mast cells, macrophages, epithelial cells, fibroblasts, and bronchial smooth muscle cells. These cells also regulate airway inflammation and initiate the process of remodeling by the release of cytokines and growth factors.

**Epithelial Cells**

Bronchial epithelial cells participate in mucociliary clearance and removal of noxious agents; however, they also enhance inflammation by releasing eicosanoids, peptidases, matrix proteins, cytokines, and nitric oxide (NO). Epithelial cells can be activated by IgE-dependent mechanisms, viruses, pollutants, or histamine. In asthma, especially fatal asthma, extensive epithelial shedding occurs. The functional consequences of epithelial shedding may include heightened airways responsiveness, altered permeability of the airway mucosa, depletion of epithelial-derived relaxant factors, and loss of enzymes responsible for degrading proinflammatory neuropeptides. The integrity of airway epithelium may influence the sensitivity of the airways to various provocative stimuli. Epithelial cells also may be important in the regulation of airway remodeling and fibrosis.

**Eosinophils**

Eosinophils play an effector role in asthma by releasing proinflammatory mediators, cytotoxic mediators, and cytokines. Circulating eosinophils migrate to the airways by cell rolling, through interactions with selectins, and eventually adhere to the endothelium through the binding of integrins to adhesion proteins (vascular cell adhesion molecule 1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]). As eosinophils enter the matrix of the membrane, their survival is prolonged by interleukin 5 (IL-5) and granulocyte-macrophage colony-stimulating factor (GM-CSF). On activation, eosinophils release inflammatory mediators such as leukotrienes and granule proteins to injure airway tissue.

**Lymphocytes**

Mucosal biopsy specimens from patients with asthma contain lymphocytes, many of which express surface markers of inflammation. There are two types of T-helper CD4+ cells. Type 1 T-helper (Th1) cells produce IL-2 and interferon-γ (IFN-γ), both essential for cellular defense mechanisms. Th2 cells produce cytokines (IL-4, -5, and -13) that mediate allergic inflammation. It is known that Th1 cytokines inhibit the production of Th2 cytokines, and vice versa. It is hypothesized that allergic asthmatic inflammation results from a Th1-mediated mechanism (an imbalance between Th1 and Th2 cells). However, more recently it has been observed that there exists a low Th2 cytokine phenotype of asthma in adults that appears more resistant to usual therapies for asthma.

**Th1 and Th2 Cell Imbalance**

The T-cell population in the cord blood of newborn infants is skewed toward a Th1 phenotype. The extent of the imbalance between Th1 and Th2 cells (as indicated by diminished IFN-γ production) during the neonatal phase may predict the subsequent development of allergic disease, asthma, or both. It has been
suggested that infants at high risk of asthma and allergies should be exposed to stimuli that upregulate Th1-mediated responses in order to restore the balance during a critical time in the development of the immune system and the lungs.

The basic premise of the hygiene hypothesis is that the newborn’s immune system needs timely and appropriate environmental stimuli to balance an immune response. Factors that enhance Th1-mediated responses include: infection with *Mycobacterium tuberculosis*, measles virus, and hepatitis A virus; increased exposure to infections through contact with older siblings; and day care attendance during the first 6 months of life. Restoration of the balance between Th1 and Th2 cells may be impeded by frequent administration of oral antibiotics, with concomitant alterations in gastrointestinal flora. Other factors favoring the Th2 phenotype include residence in an industrialized country, urban environment exposure, diet, and sensitization to house dust mites and cockroaches. Immune “imprinting” may begin in utero by transplacental transfer of allergens and cytokines.

**Mast Cells**

Mast cell degranulation is important in the initiation of immediate responses following exposure to allergens. Mast cells reside throughout the walls of the respiratory tract, and increased numbers of these cells (3- to 5-fold) have been described in the airways of allergic asthmatics. Once binding of allergen to cell-bound IgE occurs, mediators such as histamine; eosinophil and neutrophil chemotactic factors; leukotrienes (LTs) C₄, D₄, and E₄; prostaglandins; platelet-activating factor (PAF); and others are released from mast cells (see Fig. 33-2). Histologic examination has revealed decreased numbers of granulated mast cells in the airways of patients who have died from acute asthma attacks, suggesting that mast cell degranulation is a contributing factor. Sensitized mast cells are also activated by osmotic stimuli to account for exercise-induced bronchospasm (EIB).

**Alveolar Macrophages**

The primary function of alveolar macrophages in the normal airway is to serve as “scavengers,” engulfing and digesting bacteria and other foreign materials. Macrophages are found in large and small airways, ideally located for affecting the asthmatic response. A number of mediators produced and released by macrophages have been identified, including PAF, LTB₄, LTC₄, and LTD₄. Additionally, alveolar macrophages are able to produce neutrophil chemotactic factor and eosinophil chemotactic factor, which in turn amplify the inflammatory process.

**Neutrophils**

The role of neutrophils in the pathogenesis of asthma remains somewhat unclear because they normally may be present in the airways and usually do not infiltrate tissues showing chronic allergic inflammation. Neutrophils have been observed in the airways of patients who died from sudden-onset fatal asthma and in those with severe disease. Additionally, alveolar macrophages are able to produce neutrophil chemotactic factor and eosinophil chemotactic factor, which in turn amplify the inflammatory process.

**Fibroblasts and Myofibroblasts**

Fibroblasts are found frequently in connective tissue. Human lung fibroblasts may behave as inflammatory cells on activation by IL-4.
and IL-13. The myofibroblast may contribute to the regulation of inflammation via the release of cytokines and to tissue remodeling. In asthma, myofibroblasts are increased in numbers beneath the reticular basement membrane, and there is an association between their numbers and the thickness of the reticular basement membrane.\(^2,10\)

### Inflammatory Mediators

Associated with asthma for many years, histamine is capable of inducing smooth muscle constriction and bronchospasm and is thought to play a role in mucosal edema and mucus secretion.\(^2\) Lung mast cells are an important source of histamine. The release of histamine can be stimulated by exposure of the airways to a variety of factors, including physical stimuli (airway drying with exercise) and relevant allergens.\(^7\) Histamine is involved in acute bronchospasm following allergen exposure; however, other mediators such as leukotrienes are also involved.

Besides histamine release, mast cell degranulation releases interleukins, proteases, and other enzymes that activate the production of other mediators of inflammation. Several classes of important mediators, including arachidonic acid and its metabolites (i.e., prostaglandins, leukotrienes, and PAF), are derived from cell membrane phospholipids.

Once arachidonic acid is released, it can be metabolized by the enzyme cyclooxygenase to form prostaglandins. Prostaglandin \(\text{D}_2\) is a potent bronchoconstricting agent, however it is unlikely to produce sustained effects and its role in asthma remains to be determined. Similarly, prostaglandin \(\text{E}_2\) is a potent bronchoconstrictor in patients with asthma and can enhance the effects of histamine.\(^2,7\) However, its pathophysiology role in asthma is unclear. Another cyclooxygenase product, prostacyclin (prostaglandin \(\text{I}_1\)), is known to be produced in the lung and may contribute to inflammation and edema owing to its effects as a vasodilator.

Thromboxane \(\text{A}_2\) is produced by alveolar macrophages, fibroblasts, epithelial cells, neutrophils, and platelets within the lung.\(^7\) Thromboxane \(\text{A}_2\) may have several effects, including bronchoconstriction, involvement in the late asthmatic response, and involvement in the development of airway inflammation and BHR.

The 5-lipoxygenase pathway of arachidonic acid metabolism is responsible for the production of the cysteinyl leukotrienes.\(^7\) Leukotriene \(\text{C}_4\), \(\text{LTD}_4\), and \(\text{LTE}_4\) are released during inflammatory processes in the lung. Leukotrienes \(\text{D}_4\) and \(\text{E}_4\) share a common receptor (\(\text{LTD}_4\) receptor) that, when stimulated, produces bronchospasm, mucus secretion, microvascular permeability, and airway edema, whereas \(\text{LTB}_4\) is involved with granulocyte chemotaxis.

Thought to be produced by macrophages, eosinophils, and neutrophils within the lung, PAF is involved in the mediation of bronchospasm, sustained induction of BHR, edema formation, and chemotaxis of eosinophils.\(^7\)

### Adhesion Molecules

Adhesion molecules are glycoproteins that facilitate infiltration and migration of inflammatory cells to the site of inflammation. Adhesion molecules have additional functions involved in the inflammatory process aside from promoting cell adhesion, including activation of cells and cell–cell communication, and promoting cellular migration and infiltration.\(^7\) The many adhesion molecules are divided into families on the basis of their chemical structure. These families are the integrins, cadherins, immunoglobulin supergene family, selectins, vascular adrenergins, and carbohydrate ligands.\(^7\) Those thought to be important in inflammation include the integrins, immunoglobulin supergene family, selectins, and carbohydrate ligands, including ICAM-1 and VCAM-1.\(^7\)

Adhesion molecules are found on a variety of cells, such as neutrophils, monocytes, lymphocytes, basophils, eosinophils, granulocytes, platelets, endothelial cells, and epithelial cells, and can be expressed or activated by the many inflammatory mediators present in asthma.\(^7\)

### CLINICAL CONSEQUENCES OF CHRONIC INFLAMMATION

Chronic inflammation is associated with nonspecific BHR and increases the risk of asthma exacerbations. Exacerbations are characterized by increased symptoms and worsening airways obstruction over a period of days or even weeks, and rarely hours. Hyperresponsiveness of the airways to physical, chemical, and pharmacologic stimuli is a hallmark of asthma.\(^2\) BHR also occurs in some patients with chronic bronchitis and allergic rhinitis.\(^2\) Normal healthy subjects also may develop a transient BHR after viral respiratory infections or ozone exposure. However, the degree of BHR in patients with asthma is quantitatively greater than in other populations. Bronchial responsiveness of the general population fits a unimodal distribution that is skewed toward increased reactivity; individuals with clinical asthma represent the extreme end of this distribution. The degree of BHR within asthma correlates with its clinical course and medication requirement necessary to control symptoms.\(^2\) Patients with mild symptoms or in remission demonstrate lower levels of BHR.

The current understanding is that the BHR seen in asthma is at least in part due to and correlative with the extent of airways inflammation.\(^2\) Airways remodeling also correlates somewhat with BHR.\(^10\)

### REMODELING OF THE AIRWAYS

Acute inflammation is a beneficial, nonspecific response of tissues to injury and generally leads to repair and restoration of the normal structure and function. In contrast, asthma represents a chronic inflammatory process of the airways followed by healing that in some may result in altered structure referred to as remodeling.\(^10\) Repair involves replacement of injured tissue by parenchymal cells of the same type and replacement by connective tissue and its maturation into scar tissue. In asthma, remodeling presents as extracellular matrix fibrosis, an increase in smooth muscle and mucus gland mass, and angiogenesis.\(^10\)

The precise mechanisms of remodeling of the airways are under intense study. Airways remodeling is of concern because it may represent an irreversible process that can have more serious sequelae such as the development of chronic obstructive pulmonary disease (COPD).\(^2,10\) Observations in children with asthma indicate that some loss of lung function may occur during the first 5 years of life.\(^7\) Importantly, no current therapies have been shown to alter either early decreased lung growth or later progressive loss of lung function.

### MUCUS PRODUCTION

The mucociliary system is the lung’s primary defense mechanism against irritants and infectious agents. Mucus, composed of 95% water and 5% glycoproteins, is produced by bronchial epithelial glands and goblet cells.\(^7\) The lining of the airways consists of a continuous aqueous layer controlled by active ion transport across the epithelium in which water moves toward the lumen along the concentration gradient. Catecholamines and vagal stimulation enhance the ion transport and fluid movement. Mucus transport depends on its viscoelastic properties. Mucus that is either too watery or too viscous will not be transported optimally. The exudative
inflammatory process and sloughing of epithelial cells into the airway lumen impair mucociliary transport. The bronchial glands are increased in size and the goblet cells are increased in size and number in asthma. Expectorated mucus from patients with asthma tends to have a high viscosity. The mucus plugs in the airways of patients who died in status asthmaticus are tenacious and tend to be connected by mucous strands to the goblet cells. Asthmatic airways also may become plugged with casts consisting of epithelial and inflammatory cells. Although it is tempting to speculate that death from asthma attacks is a result of the mucus plugging resulting in irreversible obstruction, there is no direct evidence for this. Autopsies of asthmatics who died from other causes have shown similar pathology. In addition, some patients who have died of sudden severe asthma did not show the characteristic mucus plugging on necropsy.7

AIRWAY SMOOTH MUSCLE

The smooth muscle of the airways does not form a uniform coat around the airways but is wrapped around in a connecting network best described as a spiral arrangement.14 The muscle contraction displays a sphincteric action that is capable of completely occluding the airway lumen. The airway smooth muscle extends from the trachea through the respiratory bronchioles. When expressed as a percentage of wall thickness, the smooth muscle represents 5% of the large central airways and up to 20% of the wall thickness in the bronchioles. Total smooth muscle mass decreases rapidly past the terminal bronchioles to the alveoli, so the contribution of smooth muscle tone to airway diameter in this region is relatively small. In the large airways of asthmatics, smooth muscle may account for 11% of the wall thickness. It is possible that the increased smooth muscle mass of the asthmatic airways is important in magnifying and maintaining BHR in persistent disease. However, it appears that the hypertrophy and hyperplasia are secondary processes caused by chronic inflammation and are not the primary cause of BHR.14

NEURAL CONTROL/NEUROGENIC INFLAMMATION

The airway is innervated by parasympathetic, sympathetic, and nonadrenergic inhibitory nerves.2 Parasympathetic innervation of the smooth muscle consists of efferent motor fibers in the vagus nerves and sensory afferent fibers in the vagus and other nerves.14 The normal resting tone of human airway smooth muscle is maintained by vagal efferent activity. Maximum bronchoconstriction mediated by vagal stimulation occurs in the small bronchi and is absent in the small bronchioles. The nonmyelinated C fibers of the afferent system lie immediately beneath the tight junctions between epithelial cells lining the airway lumen.14 These endings probably represent the irritant receptors of the airways. Stimulation of these irritant receptors by mechanical stimulation, chemical and particulate irritants, and pharmacologic agents such as histamine produces reflex bronchoconstriction.7

The nonadrenergic, noncholinergic (NANC) nervous system has been described in the trachea and bronchi. Substance P, neurokinin A, neurokinin B, and vasoactive intestinal peptide (VIP) are the best characterized neurotransmitters in the NANC nervous system.7 VIP is an inhibitory neurotransmitter. Inflammatory cells in asthma can release peptidases that can degrade VIP, producing exaggerated reflex cholinergic bronchoconstriction. NANC excitatory neuro-peptides such as substance P and neurokinin A are released by stimulation of C-fiber sensory nerve endings. The NANC system may play an important role in amplifying inflammation in asthma by releasing NO.

NITRIC OXIDE

NO is produced by cells within the respiratory tract. It has been thought to be a neurotransmitter of the NANC nervous system.15 Endogenous NO is generated from the amino acid L-arginine by the enzyme NO synthase.15 There are three isoforms of NO synthase. One isoform is induced in response to proinflammatory cytokines, inducible NO synthase (iNOS), in airway epithelial cells and inflammatory cells of asthmatic airways.15 NO produces smooth muscle relaxation in the vasculature and bronchials; however, it appears to amplify the inflammatory process and is unlikely to be of therapeutic benefit. Investigations measuring the fraction of exhaled NO (FeNO) concentrations have suggested that it may be a useful measure of ongoing lower airways inflammation in patients with asthma and for guiding asthma therapy.15

CLINICAL PRESENTATION

CHRONIC ASTHMA

Classic asthma is characterized by episodic dyspnea associated with wheezing; however, the clinical presentation of asthma is as diverse as the number of triggering events (see Clinical Presentation: Chronic Ambulatory Asthma). Although wheezing is the characteristic symptom of asthma, the medical literature is replete with the warning that “not all that wheeze is asthma.” A wheeze is a high-pitched, whistling sound created by turbulent airflow through an obstructed airway, so any condition that produces significant obstruction can result in wheezing as a symptom. In addition, “all of asthma does not wheeze” is an equally justifiable warning. Patients may present with a chronic persistent cough as their only symptom.2

CLINICAL PRESENTATION: CHRONIC AMBULATORY ASTHMA

General

- Asthma is a disease of exacerbation and remission, so the patient may not have any signs or symptoms at the time of exam.

Symptoms

- The patient may complain of episodes of dyspnea, chest tightness, coughing (particularly at night), wheezing, or a whistling sound when breathing. These often occur in association with exercise, but also occur spontaneously or in association with known allergens.

Signs

- Expiratory wheezing on auscultation, dry hacking cough, or signs of atopy (allergic rhinitis and/or eczema) may occur.

Laboratory

- Spirometry demonstrates obstruction (reduced FEV1/FVC) with reversibility following inhaled β2-agonist administration (at least a 12% improvement in FEV1).

Other Diagnostic Tests

- A fall in FEV1 of at least 15% following 6 minutes of near maximal exercise. Elevated eosinophil count and IgE concentration in blood. Elevated FeNO (greater than 20 ppb in children less than 12 years of age and greater than 25 ppb in adults). Positive methacholine challenge (PC20 FEV1 less than 12.5 mg/mL) or mannitol challenge (FEV1 decrease of at least 15% from baseline after 635 mg or less).
There is no single diagnostic test for asthma. The diagnosis is based primarily on a good history (Table 33–2). The patient may have a family history of allergy or asthma or have symptoms of allergic rhinitis. Reversibility of airways obstruction following administration of a short-acting inhaled \( \beta_2 \)-agonist provides confirmation but is not by itself diagnostic. Patients with normal values of spirometry can be challenged by exercise or substances that produce bronchoconstriction, such as methacholine, to determine if they have BHR, but again, positive challenges are not diagnostic. Newer tests of inflammation in the airways such as induced sputum eosinophil counts and FeNO measurements are consistent with but not diagnostic of asthma.

Asthma has a widely variable presentation from chronic daily symptoms to only intermittent symptoms. The intervals between symptoms can be days, weeks, months, or years. Asthma also can vary as to its severity, the intrinsic intensity of the disease process. Severity is most easily and directly measured in a patient who is not currently receiving asthma treatment. The NAEPP has provided a means of classifying asthma severity that is broken down into two domains: impairment and risk. This classification system is individualized for 3 age groups (0–4 years, 5–11 years, and ≥12 years) and summarized in Table 33–3. The intermittent and/or chronic nature of symptoms does not necessarily determine the severity of symptoms during exacerbations. Asthma severity is determined by lung function, symptoms, nighttime awakenings, and interference with normal activity prior to therapy. Patients can present with a range from intermittent symptoms that require no medications or only occasional use of short-acting inhaled \( \beta_2 \)-agonists to severe persistent asthma symptoms despite treatment with multiple medications.

### ACUTE SEVERE ASTHMA

Uncontrolled asthma, with its inherent variability, can progress to an acute state where inflammation, airways edema, excessive mucus accumulation, and severe bronchospasm result in a profound airways narrowing that is poorly responsive to usual bronchodilator therapy (see Clinical Presentation: Acute Severe

Asthma). Although this progression is the most common scenario, some patients experience rapid onset or hyper-acute attacks. Hyperacute attacks are associated with neutrophilic as opposed to eosinophilic infiltration and resolve rapidly with bronchodilator therapy, suggesting that smooth muscle spasm is the major pathogenic mechanism. In most cases, ED visits for acute severe asthma represent the failure of an adequate therapeutic regimen for persistent asthma. Underutilization of antiinflammatory drugs and excessive reliance on short-acting inhaled β₂-agonists are the major risk factors for severe exacerbations. However, frequent exacerbations may represent a specific phenotype of asthma. A blunted perception of airways obstruction may predispose certain individuals to fatal asthma attacks.

### CLINICAL PRESENTATION: ACUTE SEVERE ASTHMA

**General**
- An episode can progress over several days or hours (usual scenario) or progresses rapidly over 1 to 2 hours.

**Symptoms**
- The patient is anxious in acute distress and complains of severe dyspnea, shortness of breath, chest tightness, or burning. The patient is only able to say a few words with each breath. Symptoms are unresponsive to usual measures (short-acting inhaled β₂-agonist administration).

**Signs**
- Signs include expiratory and inspiratory wheezing on auscultation (breath sounds may be diminished with very severe obstruction), dry hacking cough, tachypnea, tachycardia, pale or cyanotic skin, hyperinflated chest with intercostal and supraclavicular retractions, and hypoxic seizures if very severe.

**Laboratory**
- PEF and/or FEV₁ less than 40% of normal predicted values. Decreased arterial oxygen (PaO₂), and O₂ saturations by pulse oximetry (SaO₂ less than 90% on room air is severe). Decreased arterial or capillary CO₂ if mild, but in the normal range or increased in moderate to severe obstruction.

**Other Diagnostic Tests**
- Blood gases to assess metabolic acidosis (lactic acidosis) in severe obstruction. Complete blood count if there are signs of infection (fever and purulent sputum). Serum electrolytes as therapy with β₂-agonist and corticosteroids can lower serum potassium, magnesium, and phosphate, and increase glucose. Chest radiograph if signs of consolidation on auscultation.

### EXERCISE-INDUCED BRONCHOSPASM

During vigorous exercise, pulmonary function measurements (FEV₁ and peak expiratory flow [PEF]) in patients with asthma increase during the first few minutes but then begin to decrease after 6 to 8 minutes (Fig. 33–3). Exercise-induced bronchospasm (EIB) is defined as a drop in FEV₁, of 15% or greater from baseline (pre-exercise value). Most studies suggest that many patients with persistent asthma experience EIB. The exact pathogenesis of EIB is unknown, but heat loss and/or water loss from the central airways appears to play an important role. EIB is provoked more easily in patients with pre-existent airflow limitation and increased BHR to inhaled allergens. Studies have demonstrated increased plasma histamine, cysteinyl leukotrienes, prostaglandins and tryptase concentrations during EIB, suggesting a role for mast cell degranulation. These findings have led to the development of inhaled mannitol, an osmotic agent as an indirect pharmacologic bronchoprovocation test to assist in the diagnosis of asthma.

A refractory period following EIB lasts up to 3 hours after exercise in some patients. During this period, repeat exercise of the same intensity produces either no decrease in pulmonary function or a drop of less than 50% of the initial response. This refractory period is thought to be caused by an acute depletion of mast cell mediators and time required for their repletion. Patients with known refractoriness to exercise will still respond to histamine, so acute hyporesponsiveness of airway smooth muscle does not appear to be a factor.

EIB is believed to be a reflection of the increased BHR of asthmatics. A correlation, though not perfect, exists between EIB and reactivity to histamine, methacholine, and mannitol. Other patient groups with BHR (e.g., after viral infection, cystic fibrosis, or allergic rhinitis) show bronchoconstriction after exercise to a lesser degree (5%–10% drops) than patients with asthma (15%–40% drops). Patients will not always demonstrate the same sensitivity. During periods of remission, a decreased sensitivity to the same degree of exercise is often observed. Finally, a number of children and adults with EIB are otherwise normal, without symptoms or abnormal pulmonary function except in association with exercise. Elite athletes have a higher prevalence of EIB than the general population.

### NOCTURNAL ASTHMA

Worsening of asthma during sleep is referred to as nocturnal asthma. Patients with nocturnal asthma exhibit significant falls in pulmonary function between bedtime and awakening. Typically, their lung function reaches a nadir at 3 to 4 AM. Although the pathogenesis of this phenomenon is unknown, it has been associated with diurnal patterns of endogenous cortisol secretion and circulating epinephrine. Direct evidence for an inflammatory component to nocturnal asthma includes increased circulating histamine and activated eosinophils and leukotriene excretion at night associated with increased BHR to methacholine.

Numerous other factors that may affect nocturnal worsening of asthma, including allergies and improper environmental control, gastroesophageal reflux, obstructive sleep apnea, and sinusitis, also must be considered when evaluating these patients. Most experts consider nocturnal symptoms to be a sign of inadequately treated persistent asthma. Awakening from nocturnal asthma is a sensitive indicator of both severity and asthma control.
CHAPTER 33

VIRAL RESPIRATORY INFECTIONS

Viral respiratory infections are primarily responsible for exacerbations of asthma, particularly in children under age 10. Infants are particularly susceptible to airways obstruction and wheezing with viral infections because of their small airways. The most common cause of exacerbations in both children and adults is the common rhinovirus. Other viruses isolated include respiratory syncytial virus (RSV), parainfluenza virus, coronavirus, and influenza viruses. Certain viruses (RSV and parainfluenza virus) are capable of inducing specific IgE antibodies, and rhinovirus can activate eosinophils directly in asthmatics. The increase in asthma symptoms and BHR that occurs may last for days or weeks following resolution of the symptoms of the viral infection. Evidence does not support a beneficial effect of influenza vaccine for preventing asthma exacerbations from subsequent influenza infections.

ENVIRONMENTAL AND OCCUPATIONAL FACTORS

Agents and events and the mechanisms that are known to trigger asthma are listed in Table 33-1. The general mechanisms are unknown but presumably are the result of epithelial damage and inflammation in the airway mucosa. Ozone and sulfur dioxide, common components of air pollution, have been used to induce BHR in animals. Exposure to 0.2 ppm ozone for 2 to 3 hours can induce bronchoconstriction and increase BHR in asthmatics. Sulfur dioxide in the ambient atmosphere is highly irritating and presumably induces bronchoconstriction through mast cell or irritant-receptor involvement. Asthma produced by repeated prolonged exposure to industrial inhalants is a significant health problem. It has been estimated that occupational asthma accounts for 2% of all asthmatic persons. Persons with occupational asthma have the typical symptoms of asthma with cough, dyspnea, and wheeze. Typically, the symptoms are related to work place exposure and improve on days off and during vacations. In some instances, symptoms may persist even after termination of exposure.

STRESS, DEPRESSION, AND PSYCHOSOCIAL FACTORS IN ASTHMA

Observational studies demonstrate an association between increased stress and worsening asthma, but the role is not clearly defined. Bronchoconstriction from psychological factors appears to be mediated primarily through excess parasympathetic input. Atropine has been shown to block experimental psychogenic bronchoconstriction. It is most important to emphasize to both patients and parents that asthma is not an emotional disease; however, coping skills may benefit the patient who becomes emotionally distraught during an asthma attack.

RHINITIS/SINUSITIS

Disorders of the upper respiratory tract, particularly rhinitis and sinusitis, have been linked with asthma for many years. As many as 40% to 50% of asthmatics have abnormal sinus radiographs. However, chronic sinusitis may just represent a nonbacterial coexisting condition with allergic asthmatics because the histologic changes in the paranasal sinuses are similar to those seen in the lung and nose. Treatment of upper airway disease may optimize overall asthma control. The mechanism by which sinusitis aggravates asthma is unknown. The treatment of allergic rhinitis with intranasal corticosteroids and Cromolyn but not antihistamines will reduce BHR in asthmatic patients. It has been postulated that transport of mucus chemotactic factors and inflammatory mediators from nasal passages during allergic rhinitis into the lung may accentuate BHR.

GASTROESOPHAGEAL REFLUX DISEASE

Symptoms of gastroesophageal reflux disease (GERD) as well as asymptomatic reflux are common in both children and adults who have asthma. Nocturnal asthma may be associated with nighttime reflux. Reflux of acidic gastric contents into the esophagus is thought to initiate a vagally mediated reflex bronchoconstriction. Also of concern is that most medications that decrease airways smooth muscle tone may have a relaxant effect on gastroesophageal sphincter tone. However, treatment of reflux in asthma patients has produced inconsistent results on asthma control. The current recommendation is to initiate standard antireflux therapy in those patients exhibiting symptoms of reflux.

FEMALE HORMONES AND ASTHMA

Premenstrual worsening of asthma has been reported in as many as 30% to 40% of women in some studies, whereas worsening of pulmonary functions has been reported even in women not aware of worsening symptoms. The pathophysiology is uncertain because estrogen replacement in postmenopausal women has been shown to worsen asthma, whereas estradiol and progesterone administration have been variably reported to improve or have no effect on asthma in women with premenstrual asthma. The clinical significance of menstruation-related asthma is still unclear because some studies have reported that up to 50% of ED visits by women were premenstrual, whereas others have reported no association with menstrual phase. In general, BHR and symptoms improve in asthmatic women during pregnancy.

FOODS, DRUGS, AND ADDITIVES

Documentation in the literature of food allergens as triggers for asthma is not available. However, additives, specifically sulfites used as preservatives, can trigger life-threatening asthma exacerbations. Beer, wine, dried fruit, and open salad bars in particular have high concentrations of metabisulfites. Severe oral corticosteroid-dependent patients should be warned about ingesting foods processed with sulfites. Another additive producing bronchospasm is benzalkonium chloride, which is found as a preservative in some nebulizer solutions of antiasthmatic drugs.

Aspirin and other nonsteroidal antiinflammatory drugs can precipitate an attack in up to 20% of adults and 5% of children with asthma. The mechanism is related to cyclooxygenase inhibition, and 5-lipoxygenase inhibition can alter dose-response but not completely block the symptoms. The prevalence increases with age and severity of asthma. The greatest frequency occurs in severe corticosteroid-resistant asthmatics in their fourth and fifth decades who also have perennial rhinitis and nasal polyps (presence of several polyps). Other drugs that do not precipitate bronchospasm but which prevent its reversal are the nonselective β-blocking agents.

NUTRITIONAL FACTORS

Epidemiologic data suggest that obesity increases the prevalence of asthma and may reduce asthma control. Lung volume and tidal
volume are reduced in obesity promoting airway narrowing. Obesity also produces low-grade systemic inflammation that may act on the lung to worsen asthma. 2 The mechanism is likely the release of adipose-derived pro-inflammatory mediators such as IL-6, IL-10, eotaxin, tumor necrosis factor-α, transforming growth factors-β1, C-reactive protein, leptin, and adiponectin or a result of common predisposing dietary factors. Although not all studies find relationship between body mass index and asthma control, management of asthma in obese patients should include weight loss measures. 24

More recently it has been shown that children with vitamin D insufficiency are at greater risk of uncontrolled asthma (increased hospitalizations, BHR and eosinophil counts). 25 Vitamin D helps regulate T-cells and improves their secretion of antiinflammatory cytokines in response to corticosteroids. 25

**TREATMENT**

**Asthma**

**AEROSOL THERAPY FOR ASTHMA**

Aerosol delivery of drugs for asthma has the advantage of being site-specific and thus enhancing the therapeutic ratio. 2, 26 Inhalation of short-acting β2-agonists provides more rapid bronchodilation than either parenteral or oral administration, as well as the greatest degree of protection against EIB and other challenges. 2 Inhaled corticosteroids have been developed with rapid oral and systemic clearance to enhance lung activity and reduce systemic activity. Specific agents (e.g., cromolyn, formoterol, salmeterol, and ipratropium bromide) are only effective by inhalation. 26 Therefore, an understanding of aerosol drug delivery is essential to optimal asthma therapy. Table 33–4 lists the factors determining lung deposition of therapeutic aerosols.

**Device Determinants of Delivery**

Devices used to generate therapeutic aerosols include jet nebulizers, ultrasonic nebulizers, metered-dose inhalers (MDIs), and dry-powder inhalers (DPIs). The single most important device factor determining the site of aerosol deposition is particle size. 2 Devices for delivering therapeutic aerosols generate particles with aerodynamic diameters from 0.5 to 35 microns. 26 Particles larger than 10 microns deposit in the oropharynx, particles between 5 and 10 microns deposit in the trachea and large bronchi, particles 1 to 5 microns in size reach the lower airways, and particles smaller than 0.5 microns act as a gas and are exhaled. In asthma, the airways, not the alveoli, are the target for delivery. Respirable particles are deposited in the airways by three mechanisms: (1) inertial impaction, (2) gravitational sedimentation, and (3) Brownian diffusion. 26 The first two mechanisms are the most important for therapeutic aerosols and probably are the only factors that can be manipulated by patients.

Each delivery device within a classification generates specific aerosol characteristics, so extrapolation of delivery data from one device cannot be applied to the other devices in the class. For instance, MDIs can deliver 15% to 50% of the actuated dose; DPIs, 10% to 30% of the labeled dose; and nebulizers, 2% to 15% of the starting dose. 26 MDIs and DPIs are portable and convenient, unlike jet nebulizers. Small portable ultrasonic nebulizers have also been developed. MDIs consist of a pressurized canister with a metering valve; the canister contains active drug, low-vapor-pressure propellants such as chlorofluorocarbon (CFC) or hydrofluoroalkane (HFA), cosolvents, and/or surfactants. 26 The international ban on the production and use of CFCs (due to their ozone layer–depleting properties) will result in no CFC propelled MDIs available in the United States by December 31, 2011. With any change in the components of an MDI, the Food and Drug Administration (FDA) considers it to be a new drug that requires stability, safety, and efficacy studies prior to approval. The drug is either in solution or a suspended micronized powder. In order to disperse the suspension for accurate delivery, the canister must be shaken. The metering chamber measures a liquid volume, and therefore, the device must be held with the valve stem downward so that the chamber is covered with liquid 26 (Fig. 33–4). When the canister is actuated, the device releases the propellant and drug in a forceful spray whose particles are large (mass median aerodynamic diameter [MMAD] = 45 microns) 26 (see Fig. 33–4). As evaporation occurs, the particle size is reduced to a final MMAD of 0.5 to 5.5 microns depending on the MDI. The aerosol cloud extends about 6 inches beyond the MDI at the lowest MMAD. 26 Each MDI has different conditions for storage and durations to expiration so the pharmacist must become familiar with and counsel the patient on these factors.

The breath-actuated MDI Autohaler is cocked with a lever to “load” the dose of medication, a baffle is opened by inspiratory

![FIGURE 33-4](image-url)
pressure, and the dose is expelled from the canister metering chamber. While the need for hand-lung coordination for proper actuation is reduced significantly with breath-actuated MDIs, these devices do not allow the use of a spacer device.

Spacer devices are used frequently with an MDI to decrease oropharyngeal deposition and enhance lung delivery. However, not all spacer devices produce similar effects. The design of spacers varies from simple open-ended tubes that separate the MDI from the mouth to valved holding chambers (VHCs) with one-way valves that open during inhalation (the preferred system). A VHC allows evaporation of the propellant prior to inhalation permitting a greater number of drug particles to achieve a respirable droplet size. The air and liquid strike a baffle, creating a droplet cloud that is then inhaled. Ultrasonic nebulizer. Jet nebulizers produce an aerosol from a liquid solution placed in a cup. A tube connected to a stream of compressed air or oxygen flows up through the bottom and draws the liquid up an adjacent open-ended tube. Both produce similar degrees of lung deposition. Jet nebulizers come with their optimal operating instructions. Increasing fill volume will increase the total amount of drug delivered; however, it also will take longer for the patient to nebulize the dose. The aerosol output and lung delivery vary significantly among the commercially available jet nebulizers even when operated in the same manner. Increasing fill volume will increase the total amount of drug delivered; however, it also will take longer for the patient to nebulize the dose. The MMAD of the droplets is related directly to the gas flow, with flows of 5 to 12 L/min providing an aerosol cloud with an MMAD of 4 to 8 microns for most jet nebulizers. Each jet nebulizer comes with its optimal operating instructions.

### Patient Determinants of Delivery

(See Table 33–4)

- The most important patient factor determining aerosol deposition is inspiratory flow. High inspiratory flows increase the degree of deposition owing to impaction of particles of any

26. Other VHCs have been developed with antistatic lining.

---

2. Oropharyngeal deposition is an important factor in reducing local adverse effects (e.g., hoarseness and thrush) from inhaled corticosteroids. The change in lung delivery depends on both the MDI and the drug, where one spacer device may enhance delivery with one MDI preparation and decrease delivery with others. The use of VHCs is less likely to enhance delivery from HFA propelled MDIs. Finally, over time, holding chambers can build up static electricity that attracts small particles to the sides of the chamber, significantly reducing aerosol availability. Some spacers should be washed weekly with household detergent with a single rinse and allowed to drip dry. Other VHCs have been developed with antistatic lining.
size, thereby increasing deposition centrally (i.e., throat and large airways) and decreasing peripheral deposition. Optimal inspiratory flow for most MDIs is slow and deep (approximately 30 L/min or 5 seconds for a full inhalation). In general, DPIs require higher inspiratory flows (≥60 L/min) and a change in inhalation technique (i.e., deep, forceful inspiration) for optimal dispersion of the powder, which, in turn, increases the amount of drug delivered to the larger central airways. However, this difference in delivery may not produce clinically significant differences. Patients should be cautioned not to exhale into DPIs because this causes loss of dose and moistens the dry powder, causing aggregation into larger particles. Patient factors that cannot be controlled include interpatient variability in airway geometry (particularly the differences between children and adults) and the effects of bronchospasm, edema, and mucus hypersecretion. Mild obstruction increases aerosol deposition; however, severe obstruction probably leads to increased central deposition from impaction. The absolute delivery to the lung is not as important as consistency of delivery, assuming that a sufficient dose to produce the desired therapeutic effect is achieved. No single inhalation device is the best for all patients. Table 33–5 lists the differing characteristics of inhalation devices.

Appropriate inhalation technique is essential to achieve optimal drug delivery and therapeutic effect. The components are illustrated in Figure 33–5. Approximately 50% to 80% of a dose from MDIs and DPIs impacts on the oropharynx and is then swallowed; the rest is either left in the device or exhaled. It is important that actuation occurs during inhalation, although the time during inspiration is unimportant. Although radiolabeled studies with MDIs indicate improved delivery by holding the actuator 2 to 3 cm in front of an open mouth to allow more evaporation and less impact, physiologic studies with bronchodilators have failed to document an advantage for this method. Many patients do not use their MDIs optimally, and patient instruction with demonstration is the most effective means of improving inhaler technique. Even with instruction, up to 30% of patients, particularly young children and the elderly, cannot master the use of an MDI. For these patients, attachment of a VHC to the MDI or use of a breath-actuated MDI can improve efficacy significantly. However addition of a VHC offers no advantage in patients who can use an MDI optimally alone. Mouth rinsing following treatment with MDI- and DPI-inhaled corticosteroids is important to minimize local effects and oral absorption.

Delivery from high-resistance DPIs is more flow-dependent than from low-resistance DPIs. Thus, younger children and possibly elderly adults will have more variability in delivery from high resistance devices. Most children younger than 4 years of age cannot generate a sufficient inspiratory flow to use DPIs. Young children (<4 years) and infants generally require the use of a facemask attached to either an MDI plus VHC or nebulizer. The use of a facemask results in a reduction in lung delivery due to the portion of the aerosol inhaled nasally so the doses of drugs used in these patients is often not decreased.

### Steps for Using Your Inhaler

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Tilt your head back slightly and breathe out slowly.
4. Position the inhaler in one of the following ways (B is acceptable for those who have difficulty with A or C. G is required for breath-activated inhalers):
   - **A** Open mouth with inhaler 1 to 2 inches away.
   - **B** Use spacer/holding chamber (that is recommended especially for young children and for people using corticosteroids).
   - **C** In the mouth.
   - **D** NOTE: Inhaled dry powder capsules require a different inhalation technique. To use a dry powder inhaler, it is important to close the mouth tightly around the mouthpiece of the inhaler and to inhale rapidly.
5. Press down on the inhaler to release medication as you start to breathe in slowly.
6. Breathe in slowly (3 to 5 seconds).
7. Hold your breath for 10 seconds to allow the medicine to reach deeply into your lungs.
8. Repeat puff as directed. Waiting 1 minute between puffs may permit second puff to penetrate your lungs better.
9. Spacers/holding chambers are useful for all patients. They are particularly recommended for young children and older adults and for use with corticosteroids.

Avoid common inhaler mistakes. Follow these inhaler tips:
- Breathe out before pressing your inhaler.
- Inhale slowly.
- Breathe in through your mouth, not your nose.
- Press down on your inhaler at the start of inhalation (or within the first second of inhalation).
- Keep inhaling as you press down on inhaler.
- Press your inhaler only once while you are inhaling (one breath for each puff).
- Make sure you breathe in evenly and deeply.

NOTE: Other inhalers are becoming available in addition to those illustrated above. Different types of inhalers require different techniques.

CHAPTER 33

Asthma

TREATMENT

Acute Severe Asthma

The primary goal is prevention of life-threatening asthma by early recognition of signs of deterioration and early intervention. As such, the principal goals of treatment include:2

- Correction of significant hypoxemia
- Rapid reversal of airflow obstruction
- Reduction of the likelihood of relapse of the exacerbation or future recurrence of severe airflow obstruction
- Development of a written asthma action plan in case of a further exacerbation

These goals are best achieved by early initiation or intensification of treatment and close monitoring of objective measures of oxygenation and lung function.2 Early response to treatment as measured by the improvement in FEV$_1$ at 30 minutes following inhaled β$_2$-agonists is the best predictor of outcome.2-20 Providing adequate oxygen supplementation to maintain oxygen (O$_2$) saturations above 90% (or >95% in pregnant women and those who have coexistent heart disease) is essential. In children younger than 6 years of age, in whom lung function measures are difficult to obtain, a combination of objective (e.g., oxygen saturation, capillary CO$_2$, respiratory rate, and heart rate) and subjective measures may be used to assess severity.2

The primary therapy of acute exacerbations is pharmacologic, which includes short-acting inhaled β$_2$-agonists and, depending on the severity, systemic corticosteroids, inhaled ipratropium and O$_2$ (Figs. 33–6 and 33–7).2 It is important that therapy not be delayed, so the history and physical examination should be obtained while initial therapy is being provided. Patients at risk for life-threatening exacerbations require special attention. Risk factors include: a history of previous severe asthma exacerbations (e.g., hospitalizations, intubations, or hypoxic seizures); difficulty perceiving asthma symptoms or severity of exacerbations; comorbidities (e.g., cardiac disease, other chronic lung disease, illicit drug use, or major psycho-social/psychiatric history); use of more than two canisters per month of short-acting inhaled β$_2$-agonists; and current intake of oral corticosteroids or recent withdrawal from oral corticosteroids.2

A complete blood count may be appropriate for patients with fever or purulent sputum, but modest leukocytosis is common in asthma exacerbations due to viral infection or secondary to corticosteroid administration. Chest radiography is not recommended for routine assessment but should be obtained for patients suspected of a complicating cardiopulmonary process or another pulmonary process (pneumothorax or pulmonary consolidation).2 Serum electrolytes should be monitored if high-dose continuous inhaled or systemic β$_2$-agonists are to be used because they can produce transient decreases in potassium, magnesium, and phosphate.2 Measurement of serum electrolytes is also prudent in patients who take diuretics regularly and in patients with coexistent cardiovascular disease. The combination of high-dose β$_2$-agonists and systemic corticosteroids occasionally may result in excessive elevations of glucose and lactic acid.2

Initial response should be achieved within minutes, and most patients experience significant improvement within the first 30 to

**Assess severity**

- Patients at high risk for a fatal attack (see figure 5–2a) require immediate medical attention after initial treatment.
- Symptoms and signs suggestive of a more serious exacerbation such as marked breathlessness, inability to speak more than short phrases, use of accessory muscles, or drowsiness (see figure 5–3) should result in initial treatment while immediately consulting with a clinician.
- Less severe signs and symptoms can be treated initially with assessment of response to therapy and further steps as listed below.
- If available, measure PEF—values of 50–79% predicted or personal best indicate the need for quick-relief mediation. Depending on the response to treatment, contact with a clinician may also be indicated. Values below 50% indicate the need for immediate medical care.

**Initial treatment**

- Inhaled SABA: up to two treatments 20 minutes apart of 2–6 puffs by metered-dose inhaler (MDI) or nebulizer treatments.
- Note: Medication delivery is highly variable. Children and individuals who have exacerbations of lesser severity may need fewer puffs than suggested above.

**Good Response**

- No wheezing or dyspnea (assess tachypnea in young children).
- PEF ≥80% predicted or personal best.
- Contact clinician for followup instructions and further management.
- May continue inhaled SABA every 3–4 hours for 24–48 hours.
- Consider short course of oral systemic corticosteroids.

**Incomplete Response**

- Persistent wheezing and dyspnea (tachypnea).
- PEF 50–79% predicted or personal best.
- Add oral systemic corticosteroid.
- Continue inhaled SABA.
- Contact clinician urgently (this day) for further instruction.

**Poor response**

- Marked wheezing and dyspnea.
- PEF ≤50% predicted or personal best.
- Add oral systemic corticosteroid.
- Repeat inhaled SABA immediately.
- If distress is severe and nonresponsive to initial treatment:
  - Call your doctor AND
  - PROCEED TO ED;
  - Consider calling 9–1–1 (ambulance transport).

**To ED.**

Key: ED, emergency department; MDI, metered-dose inhaler; PEF, peak expiratory flow; SABA, short-acting beta$_2$-agonist

(quick-relief inhaler)

**FIGURE 33-6.** Home management of acute asthma exacerbation. Patients at risk for asthma-related death should receive immediate clinical attention after initial treatment. Additional therapy may be required. (From reference 2.)
60 minutes of therapy, with most patients doubling their FEV₁ or PEF. In patients ultimately admitted to the hospital, only a 10% to 20% improvement is seen within the first 2 hours. Hypoxemia, primarily a result of ventilation-perfusion mismatch, is immediately correctable by low-flow oxygen. While reversal of lung function into the normal range may take 12 to 24 hours, complete restoration takes much longer—up to 3 to 7 days. A strategy to prevent recurrence includes systemic corticosteroids and symptom or PEF monitoring. It is essential to provide the patient with a written self-management action plan for dealing with exacerbations.

Patients at risk for severe exacerbations should be taught how to use a peak-flow meter and monitor morning peak flows at home. In young children, an increased respiratory rate, increased heart rate, and inability to speak more than one or two words between breaths are signs of severe obstruction. Oxygen saturations by pulse oximetry and peak flows should be measured in all patients not completely responding to initial intensive inhaled therapy. Initially, on admission, the peak flows or clinical symptoms should be monitored every 2 to 4 hours. Prior to discharge from the ED or hospital, the patient should be given a sufficient supply of medications for self-management.

**FIGURE 33-7.** Emergency department and hospital care of acute asthma exacerbations. (From reference 2.)
of prednisone, taught the purpose of the medications and proper inhaler technique, and referred to follow-up asthma care within 1 to 4 weeks; initiation of inhaled corticosteroids (ICSs) should also be considered.2

Early recognition of deterioration and aggressive treatment are the keys to successful treatment of acute asthma exacerbations. Thus patient and/or parent education teaching self-management skills and written action plans for early institution of therapy for severe asthma exacerbations are the keys to successful treatment of acute asthma exacerbations. Thus patient and/or parent education teaching self-management skills and written action plans for early institution of therapy for severe asthma that can occur, patients and parents should be encouraged to communicate promptly with their asthma care provider during an exacerbation.

Figures 33–6 and 33–7 illustrate the recommended therapies for the treatment of acute asthma of mild, moderate, and severe exacerbations in home and emergency department/hospital settings, respectively.2 The dosages of the drugs for acute severe exacerbations are provided in Table 33–6.28 Institutions should strongly consider developing critical-pathways/treatment algorithms for their EDs because their implementation has been shown to improve outcomes and decrease the cost of care.29 Finally, it is strongly recommended that an appointment with the patient’s primary care provider be made within 1 week of the ED visit.29

Note: No advantage has been found for very-high-dose corticosteroids in acute severe asthma, nor is there any advantage for intravenous administration over oral therapy. The usual regimen is to continue the oral corticosteroid for duration of hospitalization. The final duration of therapy following a hospitalization or emergency department visit may be from 3–10 days. If patients are then started on ICSs, there is no need to taper the systemic corticosteroid dose. ICSs can be started at any time during the exacerbation. (From reference 2.)

### NONPHARMACOLOGIC AND ANCILLARY THERAPY

Infants and young children may be mildly dehydrated owing to increased insensible loss, vomiting, and decreased intake.2 Unless dehydration has occurred, increased fluid therapy is not indicated in acute asthma management because the capillary leak from cytokines and increased negative intrathoracic pressures may promote edema in the airways.2 Correction of significant dehydration is always indicated, and the urine specific gravity may help to guide therapy in young children, in whom the state of hydration may be difficult to determine.2 Chest physical therapy and mucolytics are not recommended in the therapy of acute asthma.2 Sedatives should not be given because anxiety may be a sign of hypoxemia, which could be worsened by central nervous system depressants. Antibiotics also are not indicated routinely because viral respiratory tract infections are the primary cause of asthma exacerbations.2 Antibiotics should be reserved for patients who
have signs and symptoms of pneumonia (e.g., fever, pulmonary consolidation, and purulent sputum from polymorphonuclear leukocytes). *Mycoplasma* and *Chlamydia* are infrequent causes of severe asthma exacerbations but should be considered in patients with high oxygen requirements.²

Respiratory failure or impending respiratory failure as measured by rising PaCO₂ (245 mm Hg) or failure to correct hypoxemia with supplemental oxygen therapy is treated with intubation and mechanical ventilation.²⁷ In order to prevent barotrauma and pneumothoraces from excess positive pressure, it is recommended that controlled hypventilation or permissive hypercapnia be used (correcting the hypoxemia, PaO₂ > 60 mm Hg, but allowing the PaCO₂ to rise to the high 60 mm Hg range).²⁷

### PHARMACOTHERAPY

#### β₂-Agonists

The short-acting inhaled β₂-agonists are the most effective bronchodilators and the treatment of first choice for the management of acute severe asthma.²,²⁷ Up to 66% of adults presenting to an ED require only three doses of 2.5 mg nebulized albuterol to be discharged.²⁷ Most well-controlled clinical trials have demonstrated equal to greater efficacy and greater safety of aerosolized β₂-agonists over systemic administration regardless of the severity of obstruction.²,²⁷ Systemic adverse effects, hypokalemia, hyperglycemia, tachycardia, and cardiac dysrhythmias are more pronounced in patients receiving systemic β₂-agonist therapy. Children younger than 2 years of age achieve clinically significant responses from nebulized albuterol.²,²⁹ Effective doses of aerosolized β₂-agonists can be delivered successfully through mechanical ventilator circuits to infants, children, and adults in respiratory failure secondary to severe airways obstruction.²⁹

Frequent administration of inhaled β₂-agonists (every 20 minutes or continuous nebulization) has been found to be superior to the same dosage administered at 1-hour intervals.³⁰ In the subset of more severely obstructed patients, continuous nebulization decreases the hospital admission rate, provides greater improvement in the FEV₁ and PEF, and reduces duration of hospitalization when compared with intermittent (hourly) nebulized albuterol in the same total dose.³⁰ Thus continuous nebulization is recommended for patients having an unsatisfactory response (achieving less than 50% of normal FEV₁ or PEF) following the initial three doses (every 20 minutes) of aerosolized β₂-agonists and potentially for patients presenting initially with PEF or FEV₁ values of less than 30% of predicted normal.³,³²

The doses of inhaled β₂-agonists for acute severe asthma exacerbations (see Table 33–6) have been derived empirically. The β₂-agonists follow a log-linear dose-response curve.³¹ In addition, the dose-response curve is shifted to the right by more severe bronchospasm or by increased concentrations of bronchospastic mediators, which is characteristic of functional antagonists.³ⁱ The ability to increase the dose of the short-acting aerosolized β₂-agonists by as much as 5- to 10-fold over doses producing adequate bronchodilation in chronic stable asthma is what contributes to their efficacy in reversing the bronchospasm of acute severe exacerbations. The nebulizer dose of inhaled β₂-agonists for children often is listed on a weight basis (milligrams per kilogram). However, a fixed minimal dose (2.5 mg albuterol or equivalent), as opposed to a weight-adjusted dose, is more appropriate in younger children because children younger than 5 years of age receive a lower lung dose.² Adults dosed on a weight basis demonstrate excessive cardiac stimulation, so they have fixed maximal doses² (see Table 33–6).

Initial doses of inhaled β₂-agonists can produce vasodilation, worsening ventilation-perfusion mismatch, slightly lowering oxygen saturation or PaO₂.²⁷ High-doses of inhaled β₂-agonists can produce a decrease in serum potassium concentration, an increase in heart rate, and an increase in serum glucose and lactic acid concentration.³¹ However, both children and adults receiving continuously nebulized β₂-agonists have demonstrated decreased heart rates as their lung function improves.³⁰ Thus, an elevated heart rate is not an indication to use lower doses or to avoid using inhaled β₂-agonists.

Some controversy exists concerning the most cost-effective delivery system (MDI plus VHC vs nebulization) to be used in treating acute severe exacerbations in the ED and hospital (see below).²,²⁹ The DPIs are currently not indicated for the treatment of acute severe asthma exacerbations due to the higher inspiratory flows required for adequate drug delivery.²,²⁹

#### Corticosteroids

Systemic corticosteroids are indicated in all patients with acute severe asthma exacerbations not responding completely to initial inhaled β₂-agonist administration (every 20 minutes for three to four doses).² Intravenous therapy offers no therapeutic advantage over oral administration.²,³² This therapy usually is continued until hospital discharge. Tapering the systemic corticosteroid dose following discharge from the hospital appears unnecessary, provided that patients are prescribed inhaled corticosteroids for outpatient therapy.² Most patients achieve 70% of predicted normal FEV₁ within 48 hours and 80% of predicted by 6 days after plateauing by day 3. Thus, maintaining systemic corticosteroid courses for 10 to 14 days may be unnecessarily long in some patients. Indeed, many patients not admitted to the hospital respond to 3- to 5-day courses of systemic corticosteroids. Short courses of oral prednisone (3–10 day “bursts”) have been effective in preventing hospitalizations in infants and young children.³ It is recommended that a full dose of the corticosteroid be continued until the patient’s peak flow reaches 70% of predicted normal or personal best.²

Multiple daily dosing of systemic corticosteroids for the initial therapy of acute asthma exacerbations appears warranted because receptor-binding affinities of lung corticosteroid receptors are decreased in the face of airways inflammation.³² However, patients with less severe exacerbations may be treated adequately with once-daily administration. High-dose and very-high-pulse-dose corticosteroid regimens have not been shown to enhance the outcomes in severe acute asthma but are associated with a higher likelihood of side effects.³²

Studies of ICSs in acute exacerbations of asthma have provided conflicting results. Studies have demonstrated both greater and lesser efficacy than standard doses of oral corticosteroids.³² Currently, there is insufficient evidence supporting efficacy in the ED setting, although continued research appears warranted.² There is evidence that prescribing ICSs on discharge from the ED reduces the risk of relapse.² This policy is reasonable because inflammation is the underlying cause of deterioration in most cases.²

#### Anticholinergics

Inhaled ipratropium bromide produces a further improvement in lung function of 10% to 15% over inhaled β₂-agonists alone. In children and adults, multiple-dose ipratropium bromide added to initial therapy reduces hospitalization rate in the subset of patients with a baseline FEV₁ of less than 30% of predicted.³³ Ipratropium bromide, a quaternary amine, is poorly absorbed and produces minimal or no systemic effects. Care should be used when administering ipratropium bromide by nebulizer. If a tight mask or mouthpiece is not used, the ipratropium bromide that deposits in the eyes may produce pupillary dilation and difficulty in accommodation. Ipratropium bromide is not a vasodilator, so unlike β₂-agonists it will not worsen ventilation-perfusion mismatch.³³
Alternative Therapies

The ED use of aminophylline, a moderate bronchodilator, for acute asthma has not been recommended for a number of years. Aminophylline in adults and children hospitalized with acute asthma does not enhance improvement in lung function or reduce length of hospitalization but has increased the risk of adverse effects. Adverse effects of theophylline include nausea and vomiting and potentiation of the cardiac effects of the inhaled $\beta_2$-agonists.

Magnesium sulfate is a moderately potent bronchodilator, producing relaxation of smooth muscle and central nervous system depression. The use of intravenous magnesium sulfate in patients presenting to the ED is controversial (see below). The adverse effects of magnesium sulfate include hypotension, facial flushing, sweating, nausea, loss of deep tendon reflexes, and respiratory depression. Helium is an inert gas of low density with no pharmacologic properties that can lower resistance to gas flow and increase ventilation because the low density decreases the pressure gradient needed to achieve a given level of turbulent flow, converting turbulent flow to laminar flow. Helium is given as a mixture of helium and oxygen (heliox), usually 60% to 70% helium with 30% to 40% oxygen. Heliox has been effective in some but not all clinical trials. Although heliox is free of adverse effects, its use is limited to patients with a low inspired oxygen requirement because the decrease in density generally is insignificant clinically with less than 60% helium.

The inhalational anesthetics halothane, isoflurane, and enflurane all have been reported to have a positive effect in children and adults with acute severe asthma that is unresponsive to standard medical therapy. The proposed mechanisms for inhalational anesthetics include direct action on bronchial smooth muscle, inhibition of airway reflexes, attenuation of histamine-induced bronchospasm, and interaction with $\beta_2$-adrenergic receptors. Well-controlled trials with these agents have not been completed. Potential adverse effects include myocardial depression, vasodilation, arrhythmias, and depression of mucociliary function. In addition, the practical problem of delivery and scavenging these agents in the intensive care environment as opposed to the operating room is a concern. The use of volatile anesthetics cannot be recommended based on insufficient evidence of efficacy.

Ketamine has been recommended for rapid induction of anesthesia in patients with asthma who require intubation and mechanical ventilation. Although anecdotal reports have suggested that ketamine is useful as a short-term adjunct in acute severe asthma; controlled trials have not provided evidence of efficacy. Ketamine has several significant adverse effects, including the anesthesia emergence reaction, which can alter mood and cause delirium. These emergence phenomena occur in at least 25% of patients over 16 years of age; the incidence seems to be much lower in younger patients. Other risks include an increase in heart rate, arterial blood pressure, and cerebral blood flow because of its sympathetic effects.

SPECIAL POPULATIONS

Infants and children younger than 4 years of age may be at greater risk of respiratory failure than older children and adults. Although treated with the same drugs, these younger children require the use of a facemask as opposed to a mouthpiece for delivery of aerosolized medication. Use of the facemask reduces delivery of drug to the lung by one-half so that a minimal dose is recommended as opposed to a weight-adjusted dose. The facemask should be sized appropriately and should fit snugly over the nose and mouth. Use of the “blow by” method, where the respiratory therapist or parent places the mask or extension tubing near the child’s nose and mouth, should be discouraged because holding the mask as few as 2 cm from the patient’s face reduces lung delivery of the aerosol by 80%.

DRUG CLASS INFORMATION

Short-Acting $\beta_2$-Agonists

The $\beta_2$-agonists are the most effective bronchodilators available. The $\beta_2$-adrenergic receptors are transmembrane proteins consisting of clusters of seven helices of amino acids that form the ligand-binding core. The human $\beta_2$-adrenergic receptors are polymorphic in structure, with the most common polymorphisms in the amino terminus of the receptor at amino acid positions 16 (encoding either arginine [Arg] or glycine [Gly]) and 27 (encoding either glutamine [Gln] or glutamic acid [Glu]). Some of the polymorphisms determine responsiveness to $\beta_2$-agonists, whereas others may act as disease modifiers (see below). Stimulation of $\beta_2$-adrenergic receptor activates cytoplasmic G proteins, which in turn activate adenyl cyclase to produce cyclic adenosine monophosphate (cAMP), generally thought to be responsible for the bulk of activity through activation of various proteins by cAMP-dependent protein kinase A (PKA). This activation, in turn, decreases unbound intracellular calcium, producing smooth muscle relaxation, mast cell membrane stabilization, and skeletal muscle stimulation. Despite the fact that $\beta_2$-agonists are potent inhibitors of mast cell degranulation in vitro, they do not inhibit the late asthmatic response to allergen challenge or the subsequent bronchial hyperresponsiveness. Long-term administration of $\beta_2$-agonists does not reduce BHR, confirming a lack of significant antiinflammatory activity. $\beta_2$-Adrenergic stimulation also activates Na$^+$-K$^+$-ATPase, produces gluconeogenesis, and enhances insulin secretion, resulting in a mild to moderate decrease in serum potassium concentration by driving potassium intracellularly. The chronotropic response to $\beta_2$-agonists is mediated in part by baroreceptor reflex mechanisms as a result of the drop in blood pressure from vascular smooth muscle relaxation, as well as by direct stimulation of cardiac $\beta_2$-receptors and some $\beta_2$ stimulation at high concentrations. Table 33–7 lists the pharmacologic effects of adrenergic receptor stimulation. Because $\beta_2$-receptor stimulation produces excessive cardiac stimulation, resulting in cardiac arrhythmias, and because the inotropic effect enhancing myocardial oxygen consumption leads to myocardial necrosis, there is no rationale for using non-$\beta_2$-selective agonists in the treatment of asthma.

Table 33–8 compares the various β-adrenergic agonists used in asthma in terms of selectivity, potency, oral activity, and duration of action. The β₂-agonists are functional or physiologic antagonists in that they relax airway smooth muscle regardless of the mechanism for constriction. When administered in equipotent doses, all the short-acting drugs produce the same intensity of response; the only differences are in duration of action and cardiac toxicity. The catecholamine derivatives all have the disadvantage of rapid inactivation of their 3,4-hydroxyl catechol group from catechol-O-methyltransferase found in the gastrointestinal tract, rendering them orally inactive. In addition, catecholamines are taken up rapidly into tissues by secondary uptake mechanisms that limit their receptor occupancy and thus have a shorter duration of action. All the β₂-agonists are more bronchoselective when administered by the aerosol route. Aerosol administration of the short-acting β₂-agonists provides more rapid response and greater protection against provocations that induce bronchoconstriction such as exercise and allergen challenges than does systemic administration. Differences in myocardial effects are discernible between selective and nonselective agents even when administered as aerosols, particularly at the higher doses used for acute severe asthma. The β₂-agonists also differ in efficacy or ability to activate the β₂-adrenergic receptors. Full agonists include the catecholamines while the synthetic β₂-agonists all exhibit various levels of partial agonism in the following order of fuller agonism: formoterol > albuterol > terbutaline = pirbuterol > salmeterol. Although partial agonists by definition cannot produce maximum dilation or protection as full agonists and can potentially block the effect of a full agonist, these differences have not been proven to be clinically significant.

All synthetic β₂-agonists are 1:1 racemic mixtures of two mirror images (enantiomers) owing to an asymmetric or chiral carbon. Since most physiologic functions (receptor occupancy and activation and enzymatic metabolism) are stereoselective, the (R)-enantiomers of the β₂-agonists are the most pharmacologically active isomer. While it was felt initially that the (S)-enantiomers were essentially inactive owing to the 100 to 1,000-fold potency difference between the enantiomers, studies in animal models and isolated in vitro tissue preparations have suggested that the (S)-enantiomer of albuterol may be proinflammatory and could induce BHR. However, evidence that this occurs consistently in humans or is clinically relevant is lacking (see below). The pharmacokinetics are stereoselective as well, although not predictable. (R)-Albuterol is metabolized more rapidly than (S)-albuterol, which could lead to accumulation of (S)-albuterol with continued dosing. On the other hand, (S)-terbutaline is eliminated more rapidly than (R)-terbutaline.

Both the intensity and duration of response are dose dependent, and more important, the dose-response relationship is dynamic. At increasing levels of baseline bronchoconstriction (irrespective of the stimulus), the dose-response curve is shifted to the right, and the duration of bronchodilation is decreased. This shift is reflected in the need for higher, more frequent doses in acute asthma exacerbations; the duration of protection against significant provocation is much less than the duration of bronchodilation in chronic stable asthma (see Table 33–8).

*Relative molar potency to isoproterenol: 15 = lowest potency.
*Median durations with the highest value after a single dose and lowest after chronic administration.
*Protection refers to the prevention of bronchoconstriction induced by exercise or nonspecific bronchial challenges.
essesntially blocks exercise-induced bronchospasm completely (1% vs 5% drop in FEV₁). The corticosteroids used in asthma are compared in Table 33–9. Besides acute severe asthma, systemic corticosteroids are also recommended for the treatment of impending episodes of severe asthma unresponsive to bronchodilator therapy. The effects of corticosteroids in asthma are dose and duration dependent. This pattern is true for the adverse effects as well (Table 33–10). The clinician must continually balance the toxicity of chronic systemic corticosteroid therapy with control of asthma symptoms. Because short-term (1–2 weeks) high-dose corticosteroids (1–2 mg/kg per day of prednisone) do not produce serious toxicities, the ideal use is to administer the systemic corticosteroids in a short “burst” and then to maintain the patient on appropriate long-term control therapy with ICSs (discussed below). In general, therapy for more than 5 days at doses that exceed the usual physiologic endogenous cortisol production will cause temporary aberration in adrenal cortisol release. However, this hypothalamic-pituitary-adrenal (HPA) axis suppression is short-lived (1–3 days) and readily reversible following short bursts (≤10 days) of pharmacologic doses. A maximum number of short bursts that a patient can receive probably exists, after which chronic corticosteroid side effects occur. Adult patients receiving at least eight bursts (≥10 days each) have a similar decrease in trabeular bone density as patients on daily or alternate-day corticosteroids over 1 year. Children who received four or more bursts of prednisone exhibited a subnormal response to hypoglycemic stress or adrenocorticotropic hormone (ACTH) administration and two or more bursts/year increase the risk for osteopenia in

### Systemic Corticosteroids

The corticosteroids are the most effective antiinflammatories available to treat asthma. Actions useful in treating asthma include (1) increasing the number of β₂-adrenergic receptors and improving the receptor responsiveness to β₂-adrenergic stimulation, (2) reducing mucus production and hypersecretion, (3) reducing edema and exudation. The glucocorticoid receptor is found in the cytoplasm of most body cells, explaining the multiple effects of systemic corticosteroids. There is no difference between glucocorticoid receptors found throughout the body; however, genetic differences between glucocorticoid receptors from different individuals may determine some of the variations in response. The corticosteroids are lipophilic, readily cross the cell membrane, and combine with the glucocorticoid receptor. The activated complex then enters the nucleus, where it acts as a transcription factor leading to gene activation or suppression. This leads to specific mRNA production, resulting in increased production of antiinflammatory mediators; supression of several proinflammatory cytokines such as IL-1, GM-CSF, IL-4, IL-5, IL-6, and IL-8; reducing inflammatory cell activation, recruitment, and infiltration; and decreasing vascular permeability. In addition, the activated glucocorticoid receptor complex can act directly with cytoplasmic transcription factors, nuclear factor κB, and activating protein 1 to prevent the action of proinflammatory cytokines on the cell. Owing to the mechanism that modifies gene expression, the time required to see the particular effect depends on the time required for new protein synthesis, decreased formation of the particular mediator, and resolution of the inflammatory response. Generally, the cellular and biochemical effects are immediate, but varying amounts of time are required to produce a clinical response. β₂-Receptor density increases within 4 hours of corticosteroid administration. Improved responsiveness to β₂-agonists occurs within 2 hours. In acute severe asthma, 4 to 12 hours may be required before any clinical response is noted. Reversal of seasonally increased BHR requires at least 1 week of therapy. The chronic use of corticosteroids does not induce a state of corticosteroid dependence. Nor is there evidence of tolerance produced by chronic administration.

children. Very short courses (3–5 days) have been effective in reducing hospitalization from acute exacerbations. Use of the shorter-acting corticosteroids such as prednisone will produce less adrenal suppression than the longer-acting dexamethasone.

**Anticholinergics**

The anticholinergic agents have a long history of use for asthma, but they do not have a FDA labeled indication for asthma. Anticholinergics are competitive inhibitors of muscarinic receptors. Unlike β₂-agonists, they are not functional antagonists; they only reverse cholinergic-mediated bronchoconstriction. Normal bronchial tone is maintained through parasympathetic innervation of the airways via the vagus nerve. A number of the triggers and mediators of asthma (i.e., histamine, prostaglandins, sulfur dioxide, exercise, and allergens) produce bronchoconstriction in part through vagal reflex mechanisms. Studies consistently demonstrate that anticholinergics are effective bronchodilators in asthma, although not as effective as β₂-agonists. Anticholinergics attenuate but do not block allergen-induced asthma in a dose-dependent fashion and have no effect on BHR. Anticholinergics attenuate but do not block EIB.

Ipratropium bromide is a nonselective muscarinic receptor blocker, and blockade of inhibitory muscarinic receptors theoretically could result in an increased release of acetylcholine and overcome the block on the smooth muscle receptors (M₃). Only the quaternary ammonium derivatives such as ipratropium bromide should be used because they have the advantage of poor absorption across mucosae and the blood–brain barrier. This attribute contributes to negligible systemic effects with a prolonged local effect (i.e., bronchodilation). In addition, the quaternary compounds do not appear to produce a decrease in mucociliary clearance. Ipratropium bromide has a duration of action of 4 to 8 hours. Both intensity and duration of action are dose dependent. Tiotropium bromide, a long-acting inhaled anticholinergic with duration of 24 hours, is more selective for M₃ and M₂ receptors and less likely to affect the inhibitory M₂ receptors. Time to reach maximum bronchodilation for ipratropium is considerably slower than from aerosolized short-acting β₂-agonists (30–60 minutes vs 5–10 minutes). However, this difference is of little clinical consequence because some bronchodilation is seen within 30 seconds; 50% of maximum response occurs within 3 minutes. Ipratropium bromide is only indicated as adjunctive therapy in acute severe asthma not completely responsive to β₂-agonists alone because it does not improve outcomes in chronic asthma. Tiotropium studies in chronic asthma are ongoing.

**PHARMACOECONOMICS**

Emergency department visits for asthma exceed the number of hospitalizations by approximately 4 times, yet the annual expenditures for ED visits remain significantly less than that spent on in-patient hospital services for patients with acute severe asthma. Thus, reducing the number of patients requiring hospitalizations is a primary goal of therapy. Since the primary drugs used to treat acute severe asthma are available generically, drug costs account for only a small portion of the overall costs of care. Few of these therapies have been evaluated formally for their pharmacoeconomic impact. One evaluation based on a meta-analysis of inhaled anticholinergics added to short-acting inhaled β₂-agonists in children with acute severe asthma suggested that this approach was cost-effective and would reduce overall costs by reducing hospitalizations. In children with acute severe asthma admitted to an intensive care unit, the use of continuously nebulized albuterol resulted in a decreased cost of care compared with intermittent nebulization.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Figures 33–6 and 33–7 provide the monitoring parameters for acute severe asthma. Lung function, either spirometric or peak flow measurements, should be monitored 5 to 10 minutes after each treatment. Oxygen saturations can be easily monitored continuously with pulse oximetry. For young children and infants, pulse oximetry, lung auscultation, and observation of the presence of supraventricular retractions are useful. The majority of patients will respond within the first hour of initial inhaled β₂-agonists regardless of history of home administration of drug. Patients not achieving an initial response should be monitored every half hour to 1 hour. Depending on whether there is a standard ED or a special unit for acute severe asthma, the decision to admit to the hospital should be made within 4 to 6 hours of entry to the emergency department. The mean duration of hospitalization following admission is 2 to 3 days. Frequency of monitoring depends on the severity of the exacerbation. With mild exacerbations, monitor lung function every 2 to 3 hours and severe exacerbations every half hour to 1 hour.

**CLINICAL CONTROVERSIES**

Some clinicians believe that intravenous magnesium sulfate is effective for the treatment of acute severe asthma exacerbations unresponsive to standard doses of inhaled β₂-agonists in the ED. This belief is based on subset analyses of two studies showing that patients with the most severe obstruction following initial inhaled β₂-agonists demonstrated a reduction in hospitalizations with magnesium treatment compared with placebo. However, the subset with severe obstruction is the one demonstrating an improved response to the addition of ipratropium bromide and continuous nebulization of inhaled β₂-agonists. In addition, a large, randomized trial failed to confirm a decrease in hospitalization even in the severe group. The 2007 NAEPP guidelines state that magnesium can be considered for use in patients with severe episodes with a poor response to initial inhaled β₂-agonists.

Numerous studies have shown that the inhaled β₂-agonists administered by MDI plus VHC provide a similar outcome in acute severe asthma as drug administration by jet nebulizers. Proponents of administration by MDI plus VHC argue that it is more cost-effective and should replace nebulizer therapy. However, appropriate cost analyses have yet to be performed. Comparisons in the most severe subsets with combination therapy and continuous nebulization have not been done. Current practice should be based on the comfort level of the clinical staff until sufficient data are available to warrant a wholesale recommendation of one method.

**TREATMENT**

**Chronic Asthma**

The diagnosis of chronic asthma is made primarily by history and confirmatory spirometry (see Clinical Presentation above). The NAEPP has provided a list of questions that would lead to the diagnosis of asthma (see Table 33–2). In the older child and adult patient in whom spirometric evaluations can be performed, failure of pulmonary functions to improve acutely does not necessarily rule out asthma. Patients with long-standing disease or substantial inflammation may require an intensive, prolonged
course of bronchodilators and glucocorticoids before reversibility is detected.\(^2\) If baseline spirometry is normal, challenge testing with exercise, histamine, methacholine, or mannitol can be used to elicit BHR.\(^2\) Patients with significant symptoms and/or an FEV\(_1\) of less than 70% of predicted normal should not be challenged. Vocal cord dysfunction, particularly with exercise, may mimic asthma symptoms.\(^2\) Studies for atopy such as serum IgE and sputum and blood eosinophil determinations are not necessary to make the diagnosis of asthma, but they may help differentiate asthma from chronic bronchitis in adults. Clinically, this distinction is often difficult to make. Some patients with chronic bronchitis may have a reversible component, and some patients with long-standing severe chronic asthma may have significant irreversible damage and obstruction. Very high peripheral blood eosinophil counts may point to the diagnosis of allergic bronchopulmonary aspergillosis (ABPA) or other hypereosinophilic syndromes.\(^2\) Skin testing is of no value in diagnosing asthma but is useful in identifying triggers.\(^1\) In small infants unable to perform spirometry, the diagnosis is more difficult. Hyperinflation may be demonstrated on the chest roentgenogram.\(^2\) Radiologic examination is helpful in ruling out other causes of wheezing (e.g., foreign-body aspiration, parenchymal lung disease, cardiac disease, and congenital anomalies).\(^1\) In place of pulmonary function measures, the parents should be given a diary card to record symptoms and precipitating events.

### GOALS FOR MANAGING ASTHMA LONG-TERM

The NAEPP has provided key points for managing asthma long term.\(^2\) The goal for therapy is to control asthma by:

**Reducing impairment**

1. Prevent chronic and troublesome symptoms (e.g. coughing or breathlessness in the daytime, in the night, or after exertion)

2. Require infrequent use (≤2 days a week) of short-acting inhaled β\_2-agonist for quick relief of symptoms\(^2\) (not including prevention of EIB)

3. Maintain (near) normal pulmonary function

4. Maintain normal activity levels (including exercise and other physical activity and attendance at work or school)

5. Meet patients’ and families’ expectations of and satisfaction with asthma care

**Reducing risk**

1. Prevent recurrent exacerbations of asthma and minimize the need for ED visits or hospitalizations

2. Prevent loss of lung function; for children, prevent reduced lung growth

3. Minimal or no adverse effects of therapy

### NONPHARMACOLOGIC THERAPY

Although the mainstay of the management of asthma is pharmacologic therapy, it is likely to fail without concurrent attention to relevant environmental control and management of comorbid conditions. **Figure 33–8** depicts the stepwise approach for managing asthma recommended in the newest update by the NAEPP.\(^2\) Nonpharmacologic aspects of therapy are incorporated into the steps. The guidelines were designed to give primary healthcare providers a framework with which to develop the proper approach to the individualized therapy of patients. The heterogeneity of asthma demands an individualized approach to therapy with the basic goals of therapy as primary outcome measures.\(^2\) The focus of therapy is the prevention and suppression of the underlying inflammation.\(^2\) Thus current therapeutic options in asthma consist of acute reliever medications used for acute symptoms and exacerbations and long-term control medications used for the prevention

---

**FIGURE 33-8.** Stepwise approach for managing asthma in adults and children 0 to 4 years old and 5 to 11 years old. (From reference 2.)
Patient education and environmental control at each step
Step 2–4: Consider SQ allergen immunotherapy for allergic patients

Quick-Relief Medication for All Patients
- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of systemic oral corticosteroids may be needed.
- Use of beta2-agonist >2 days a week for symptom control (not prevention of EIB) indicates inadequate control and the need to step up treatment.
of symptoms and exacerbations and the suppression of inflammation and reduction of BHR.\textsuperscript{2}

The development of a partnership in care through patient education and the teaching of patient self-management skills should be the cornerstone of any treatment program.\textsuperscript{2} There are a number of published self-management programs for children and adults available through local American Lung Association chapters, as well as asthma treatment centers, and nationally through the NAEPP and the Asthma and Allergy Foundation of America.\textsuperscript{2} Asthma self-management programs have been shown to improve patient adherence to medication regimens, improve self-management skills, and improve use of healthcare services.\textsuperscript{46,47}

Table 33–11 lists the key educational messages recommended by the NAEPP.\textsuperscript{2}

Self-management programs instruct patients in the pathogenesis of asthma and the appropriate use of their medications but focus principally on teaching patients to recognize triggers for their asthma and how to recognize early signs of deterioration.\textsuperscript{46} Home PEF monitoring is part of some programs.\textsuperscript{2} However, routine PEF monitoring in and of itself does not improve patient outcomes.\textsuperscript{2}

The NAEPP advocates the use of PEF monitoring only for patients with severe persistent asthma who have difficulty perceiving airway obstruction.\textsuperscript{2} The NAEPP also has recommended a system based on a traffic light scenario (based on percentage of normal predicted values or personal best values): The green zone is equal to 80% to 100%, the yellow zone is equal to 50% to 79%, and the red zone is less than 50%. The yellow zone is cautionary and requires increasing as-needed bronchodilator use and possibly beginning prednisone if not improved, whereas the red zone warrants contacting the patient’s healthcare provider.\textsuperscript{2}

Patient education is essential before monitoring can be effective. Patient education has proved successful regardless of the health professional who provided the information (physician, nurse, or pharmacist). The NAEPP advocates significant involvement of all points of patient care in the educational process.\textsuperscript{2} The provision of written action plans enhances the success of education and is considered an essential component of care.\textsuperscript{2} Samples of clinically tested written action plans are available from NAEPP guidelines and other sources.\textsuperscript{2}

### PHARMACOLOGIC THERAPY

The current NAEPP recommendations for therapy of persistent asthma are illustrated in Figure 33–8.\textsuperscript{2} Therapy should be adjusted based on control status of the patient (refer to later section). Regardless of the long-term therapy, all patients need to have quick-relief medication in the form of short-acting inhaled $\beta_2$-agonists available for acute symptoms. The ICSs are considered the preferred long-term control therapy for persistent asthma in all patients due to their potency and consistent effectiveness.\textsuperscript{2} Low-to-medium-dose ICSs reduce BHR, improve lung function, and reduce severe exacerbations leading to emergency department visits and hospitalizations. They are more effective than cromolyn, theophylline, or the leukotriene receptor antagonists.\textsuperscript{3} In addition, the ICSs are the only therapy that reduces the risk of dying from asthma.\textsuperscript{48}

In the low to medium doses recommended by NAEPP guidelines (Table 33–12), ICSs are safe for long-term administration (see below).\textsuperscript{2,41} The ICSs do not appear to reduce airway remodeling and loss of lung function found in some patients with persistent asthma. The ICSs do not enhance lung growth in children with asthma, prevent the development of asthma in high risk infants, nor do they induce remission of asthma as BHR and other measures of inflammation return to pretreatment levels upon discontinuation of therapy.\textsuperscript{49,50} The sensitivity and consequent clinical response to ICSs can vary among patients.\textsuperscript{2}

Although studies of the alternative long-term control therapies (e.g., cromolyn, leukotriene receptor antagonists, and theophylline) demonstrate improvement in symptoms, lung function, and as-needed, short-acting inhaled $\beta_2$-agonist use, they do not reduce BHR, suggesting minimal antiinflammatory activity.\textsuperscript{2} The evidence suggests minimal to no differences in efficacy between these alternatives. Therefore, NAEPP lists them in alphabetical order to show no preference of one over the other.\textsuperscript{2}

For those patients inadequately controlled on low dose ICSs either an increased dose of the ICS or the combination of ICS and long-acting inhaled $\beta_2$-agonist (LABA) is the next step to gain control of more moderate persistent asthma.\textsuperscript{2} Alternatives could be the addition of leukotriene modifiers or theophylline to ICSs.\textsuperscript{2} The addition of theophylline or leukotriene modifiers to ICSs is no more effective than doubling the dose of the ICS.\textsuperscript{2} The combination of ICS/LABA is more effective at reducing severe asthma exacerbations than doubling the dose of ICS in moderate persistent asthma; increasing the dose of ICSs 4-fold also will result in a significant reduction in exacerbations.\textsuperscript{51,52} However, doses of ICSs in the high range significantly enhance the risk of toxicity.\textsuperscript{41,49}

Thus, high doses of ICSs plus LABA are reserved for patients with severe persistent asthma.\textsuperscript{2}
 Although the addition of a third controller medication is often used clinically in patients with severe persistent asthma uncontrolled on high dose ICS/LABA, there are few studies evaluating this practice. 2 Leukotriene receptor antagonists or theophylline added to high-dose combination ICS/LABA do not improve outcomes. 2 Omalizumab, a recombinant anti-IgE has demonstrated significant activity in these severe uncontrolled atopic patients. 2,5

### SPECIAL POPULATIONS

Children younger than 5 years of age have not been studied adequately. Thus, many of the recommendations in this age group are extrapolated from older children and adults. 2 The studies of ICSs in this younger group demonstrate improvement in symptoms, as needed bronchodilator use, and exacerbations. The nebulized suspension of budesonide gained FDA approval from three pivotal pharmacokinetic studies establishing doses but not on efficacy although extrapolation from older children and adults. 2 The studies of ICSs are extrapolated adequately, except for pharmacokinetics. 2 Combination therapy of any kind has not been studied except for a small number of patients down to 4 years of age on ICS/LABA. 2

The FDA approval of the fluticasone/salmeterol DPI 100/50 in patients 4 to 11 years of age was based on safety and pharmacokinetic studies establishing doses but not on efficacy although improvement in symptoms and as needed bronchodilators was noted. 2 Theophylline has not been evaluated adequately, except for pharmacokinetics. 2 Combination therapy has been inadequately studied to date in this population.

Owing to the increased risk of osteoporosis and cataracts in the elderly, patients requiring high doses of ICSs should have routine bone mineral density determinations and ophthalmic exams. 2,5

Appropriate therapies for prevention of osteoporosis should be instituted. 2,5

Asthma affects 7% of pregnant women, making it potentially the most common serious medical condition to complicate pregnancy. 19 Maternal asthma has been reported to increase the risk of perinatal mortality, preeclampsia, preterm birth, and low-birthweight infants. 2,5 More severe asthma is associated with increased risks, whereas better-controlled asthma is associated with decreased risks. A systematic review of the evidence on the safety of asthma medications has concluded that it is safer for pregnant women with asthma to be treated with effective medications than for them to have exacerbations. 19 Proper monitoring and control of asthma should enable a woman with asthma to maintain a normal pregnancy with little or no risk to mother or her fetus.

A stepwise approach to managing asthma during pregnancy and lactation has been published, with low-dose ICSs recommended as preferred treatment for mild persistent asthma with the addition of a LABA if not adequately controlled. 19 Budesonide is considered the preferred ICS to initiate because it has the greatest amount of safety data. 19 Albuterol is considered the preferred rescue therapy. 19

### DRUG CLASS INFORMATION

#### Inhaled Corticosteroids

The mechanism of action of the corticosteroids has been reviewed (see above). The principal advantage of the ICSs is their high topical potency to reduce inflammation in the lung and low systemic activity. 41 The ICSs have high antiinflammatory potency, approximately 1,000-fold greater than endogenous cortisol, and differ from each other by as much as 4- to 6-fold. 41 However, potency differences, which are simply a measure of binding affinity to the...
receptor, can be overcome simply by giving different microgram dosages of drug. Aerosol delivery of the preparations is remarkably variable, ranging from 10% to 60% of the nominal dose (i.e., that dose which leaves an actuator for an MDI or, in the case of a DPI, that which is released on actuation of the inhaler).\textsuperscript{20,41} Different devices for the same chemical entity may result in 2-fold differences in delivery, so that delivery method can make a significant difference in the relative comparable dose or therapeutic index.\textsuperscript{2,41}

The ICSs, beclomethasone dipropionate, budesonide, ciclesonide, flunisolide, fluticasone propionate, and mometasone furoate, that are currently available for use are compared and listed in Table 33–12. The ICSs have pharmacokinetic differences that result in different topical/systemic activity.\textsuperscript{41} Most evidence is consistent with log-linear dose-response curves for both indirect and direct responses.\textsuperscript{49} The log-linear nature of the dose-response curve for ICS activity raises the issue of how much of a difference in dose (or ability, and prolonged residence time in the lung).\textsuperscript{41} Owing to their selectivity include rapid systemic clearance, poor oral bioavailability, and the lowest therapeutic index when administered by MDI plus VHC.\textsuperscript{3,41} Although ciclesonide and its active metabolite have rapid systemic clearance suggesting an improved therapeutic index it has not yet been clearly established in clinical trials.\textsuperscript{41}

The response to ICSs is somewhat delayed. Most patients’ symptoms will improve in the first 1 to 2 weeks of therapy and reach maximum improvement in 4 to 8 weeks.\textsuperscript{41} Improvement in baseline FEV\textsubscript{1} and PEF may require 3 to 6 weeks for maximum improvement, whereas improvement in BHR requires 2 to 3 weeks and approaches maximum in 1 to 3 months but may continue to improve over 1 year.\textsuperscript{2,41} Most of the improvement in these parameters occurs at low to medium doses, and there is a large variability in response, with 10% of patients not demonstrating an improvement in either parameter.\textsuperscript{41} Whether these nonresponders also show no improvement in rates of exacerbations is unknown. Maximum decrease in FeNO occurs within 2 to 3 weeks.\textsuperscript{15,49} Sensitivity to exercise challenge decreases after 4 weeks of therapy.\textsuperscript{41} Although single doses do not inhibit the immediate asthmatic response to antigen challenge, continued therapy for 1 week partially suppresses the response. These two latter effects are likely due to a reduction in mucosal mast cells.\textsuperscript{49}

Local adverse effects from ICSs include oropharyngeal candidiasis and dysphonia that are dose-dependent. The dysphonia (reported in 5%–20% of patients) appears to be due to a local corticosteroid-induced myopathy of the vocal cords.\textsuperscript{21} The use of a spacer device with MDIs can decrease oropharyngeal deposition and thus decrease the incidence and severity of local side effects.\textsuperscript{2,49} In infants who require ICS delivery through a facemask, the parent should clean the nasal-perioral area with a damp cloth following each treatment to prevent topical candidal infections.

Systemic adverse effects can occur with any of the ICSs given in a sufficiently high dose.\textsuperscript{49} Long-term adverse effects of greatest concern include growth suppression in children, osteoporosis, cataracts, dermal thinning, and adrenal insufficiency and crisis.\textsuperscript{49} Of these, only growth retardation occurs in low to medium doses. However, the growth reduction appears to be transient in that growth velocity is reduced in the first 6 months to 1 year of therapy and then returns to normal.\textsuperscript{2,49} The effect is small (1–2 cm total) and not cumulative, and current studies suggest that attainment of predicted adult height is not affected.\textsuperscript{2,49} The suppression of the hypothalamic-pituitary-adrenal axis and decreased bone mineralization are dose dependent and do not appear to be significant clinically except at high doses.\textsuperscript{49} The risks therefore depend on the therapeutic index of each ICS and its delivery device. The effect of delivery device is illustrated by fluticasone propionate, which has both the greatest therapeutic index when administered by DPI and the lowest therapeutic index when administered by MDI plus VHC.\textsuperscript{3,49} Many of the ICSs, including fluticasone propionate, budesonide, ciclesonide, and mometasone furoate, are metabolized in the gastrointestinal tract and liver by CYP3A4 isoenzymes. Potent inhibitors of CYP3A4 such as ritonavir and ketoconazole have the potential for increasing systemic concentrations of these ICSs by increasing oral availability and decreasing systemic clearance.\textsuperscript{41} Some cases of clinically significant Cushing syndrome and secondary adrenal insufficiency have been reported.\textsuperscript{41}

Most patients with moderate disease can be controlled with twice-daily dosing of most ICSs.\textsuperscript{2,41} Twice-daily dosing produces less

oral bioavailability is obviated by using a spacer device with the MDI for the drugs with higher oral bioavailability because appropriate spacers reduce the oral dose by 80%.\textsuperscript{41} The use of VHCs also can increase systemic activity by increasing lung delivery of drugs not absorbed significantly orally.\textsuperscript{41} If this increase in lung deposition is 2-fold or less, it will increase systemic activity without producing a clinically important increase in efficacy, thus decreasing the therapeutic index.\textsuperscript{41} Mouth rinsing and spitting will also reduce the oral availability and are particularly useful for DPI devices.\textsuperscript{2,41}
Long-Acting Inhaled $\beta_2$-Agonists

The two LABAs, formoterol and salmeterol, provide long-lasting bronchodilation (≥12 hours) when administered as aerosols. The two LABAs, formoterol and salmeterol, provide long-lasting bronchodilation when administered as aerosols. The LABAs are preferred adjunctive therapy to ICSs in children 12 years and older and adults for step 3 and children 5 to 11 years of age for steps 4 and 5. Combination treatment with ICS/LABA provides greater asthma control than increasing the dose of ICS alone, while at the same time reducing the frequency of mild and severe exacerbations. Since they are devoid of anti-inflammatory activity, LABAs should not be used as monotherapy for asthma. Patients treated with LABA monotherapy added to usual therapy are at an increased risk for severe, life-threatening exacerbations and asthma-related death. This risk may be greater in African American patients. Whether this risk is obviated by concomitant ICS use is unknown at this time but current evidence does not support an increased risk of severe, life-threatening exacerbations in patients receiving LABAs in combination with ICSs. A recent controlled study failed to detect lung function deterioration or increased exacerbations in Arg-16 homozygotes receiving a LABA plus ICS. As with short-acting $\beta_2$-agonists, tolerance is produced with chronic administration of LABAs. Long-term trials have shown no diminution in bronchodilator response but a partial loss of bronchoprotective effect against methacholine, histamine, and exercise challenge. In particular, the duration of protection against EIB following a single dose of salmeterol is up to 9 hours but is reduced to less than 4 hours following regular treatment. Following regular treatment with LABAs, decreased protection against nonspecific bronchoprovocation with methacholine also occurs, although they continue to provide greater protection than placebo. Responsiveness to short-acting $\beta_2$-agonists has been reported to be slightly decreased but easily overcome by increasing the dose (by approximately one puff) following chronic therapy with LABAs.

There is ample evidence that the use of a LABA in combination with ICS therapy does not mask inflammation. In children 4 to 11 years of age, LABAs added to ICS reduce impairment but have yet to be adequately studied for reducing the risk domain of exacerbations over ICS alone. In children 0 to 4 years, the LABA/ICS combination has not been studied.

Methylxanthines

Methylxanthines have been used for asthma therapy for more than 50 years, but their use in recent years has declined markedly owing to the high risk of severe life-threatening toxicity and numerous drug interactions, as well as decreased efficacy compared with ICSs and LABAs. Theophylline, the primary methylxanthine of interest, is a moderately potent bronchodilator with mild anti-inflammatory properties. Like the $\beta_2$-agonists, the methylxanthines are functional antagonists of bronchospasm; however, their clinical utility is limited by their low therapeutic index. Theophylline as a sustained-release product is the preferred oral preparation, whereas its complex with ethylendiamine (aminophylline) is the preferred injectable product owing to increased solubility.

The mechanism by which theophylline produces bronchodilation appears to be through nonselective phosphodiesterase inhibition—producing increased cAMP and cyclic guanosine monophosphate (cGMP) concentrations. The phosphodiesterase (PDE) isoenzymes currently thought to be important for theophylline’s clinical effects are isoenzymes III, predominant in airway smooth muscle, and IV, important in inflammatory cell regulation such as mast cells, neutrophils, eosinophils, and T-lymphocytes. Selective PDE isoenzyme IV inhibitors, however, have no significant effects in clinical asthma. Theophylline also activates histone deacetylase that is involved in the corticosteroid-induced decrease in proinflammatory gene expression. Theophylline is a competitive antagonist of adenosine and stimulates endogenous catecholamine release which are important determinants of toxic symptoms of excess theophylline.

Theophylline has a log-linear dose-response curve. Most chronic stable patients with asthma will obtain significant bronchodilation when the serum theophylline concentration reaches 5 mcg/mL, and most patients will have no toxic symptoms with serum concentrations of less than 15 mcg/mL. The percentage of patients experiencing adverse effects increases sharply as concentrations exceed 15 mcg/mL. As with the $\beta_2$-agonists, the dose-response curves for smooth muscle relaxation by theophylline are dynamic and shifted to the right in the face of increasing contractile stimuli. This property probably explains theophylline’s relative lack of bronchodilatory effect in acute severe asthma. The severity of theophylline’s toxicity precludes even doubling the usual dosage. Toxicities include caffeine-like effects of nausea, vomiting, tachycardia, jitteriness, and difficulty sleeping to more severe toxicities such as cardiac tachyarrhythmias and seizures. Death has occurred in children receiving their usual doses of theophylline during acute systemic viral illnesses.

Routine monitoring of serum concentrations is essential for the safe and effective use of theophylline. Theophylline is eliminated primarily by metabolism via the hepatic cytochrome P450 mixed-function oxidase microsomal enzymes (primarily the CYP1A2 and CYP3A4 isozymes), with 10% or less excreted unchanged in the kidney. Theophylline clearance is age-dependent, with 1- to 9-year-olds having the highest systemic clearances and therefore...
CHAPTER 33
Algorithm for slow titration of theophylline dosage and guide for final dosage adjustment based on serum theophylline concentration measurement. For infants younger than 1 year of age, the initial daily dosage can be calculated by the following regression equation: Dose (mg/kg) = (0.2) (age in weeks) + 5.0. Whenever side effects occur, dosage should be reduced to a previously tolerated lower dose.

![FIGURE 33-9. Algorithm for slow titration of theophylline dosage and guide for final dosage adjustment based on serum theophylline concentration measurement.](image)

Requiring the largest dosages (on a weight basis). However, even within the same age groups, theophylline clearance can vary 2- to 3-fold. Figure 33–9 outlines a dosing and monitoring schedule for theophylline. Factors affecting theophylline's hepatic metabolism are listed in Table 33–14. Only drugs or diseases that produce a ≥20% inhibition or a ≥50% induction of theophylline metabolism are likely to result in clinically significant interactions.

Sustained-release theophylline is less effective than ICSs and no more effective than oral sustained-release β2-agonists, cromolyn, or leukotriene antagonists. The addition of theophylline to ICSs is similar to doubling the dose of the ICS and is overall less effective than the LABAs as adjunctive therapy. The addition of theophylline to patients with poorly controlled asthma receiving ICS/LABA combination does not improve outcomes.

**Cromolyn Sodium**

Cromolyn is classified as a mast cell stabilizer and inhibits the early and late asthmatic response to allergen challenge, as well as inhibiting exercise-induced bronchospasm. Treatment prevents the usual rise in BHR with specific pollen seasons, but long-term treatment produces minimal to no change in baseline BHR. Cromolyn inhibits neurally mediated bronchoconstriction through C-fiber sensory nerve stimulation in the airways, although it does not have a bronchodilatory effect.

Cromolyn is only effective by inhalation. It is not bioavailable orally, but the portion of the dose that reaches the lung is absorbed completely. Absorption from the airway is significantly slower than elimination (hours vs minutes). The short duration in the lung likely limits its efficacy. Both the intensity and duration of protection against various challenges are dose dependent.

Cromolyn is remarkably nontoxic. No evidence of mutagenesis or teratogenesis has been found. Cough and wheeze have been reported following inhalation. Tolerance to cromolyn has not been demonstrated. It is not considered to be an ICS-sparing agent.

Cromolyn is no more or less effective than theophylline or the leukotriene antagonists for persistent asthma. Cromolyn is not as effective as the ICSs for controlling persistent asthma. Cromolyn is not as effective as the inhaled β2-agonists for preventing EIB but can be used in conjunction for patients not responding completely to the inhaled β2-agonists.

Most patients will experience an improvement in 1 to 2 weeks, but it may take longer to achieve maximum benefit. Patients initially should receive cromolyn 4 times daily, and then only after stabilization of symptoms may the frequency be reduced to 3 times daily.

**Leukotriene Modifiers**

Two cysteinyl leukotriene receptor antagonists (zafirlukast and montelukast) and one 5-lipoxygenase inhibitor (zileuton) are available in the United States. In challenge studies, they reduce allergen-, exercise-, cold-air hyperventilation-, irritant-, and aspirin-induced asthma. Clinical use of zileuton is limited due to the potential for elevated liver enzymes (especially in the first 3 months of therapy), and the potential inhibition of drugs metabolized by the CYP3A4 isoenzymes. They are not preferred alternatives in mild persistent asthma nor as alternative add-on therapy for moderate persistent asthma (Fig. 33–8).

These drugs improve pulmonary function tests (FEV1 and PEF), decrease nocturnal awakenings and β2-agonist use, and improve asthma symptoms. A major advantage is that they are effective orally, and can be administered once or twice a day. However, they are less effective in asthma than low doses of ICSs. Although montelukast is approved for EIB in adults, it is significantly less effective than short-acting inhaled β2-agonists. In adults with severe uncontrolled asthma they do not improve outcomes. They are not as effective as LABAs when added to ICSs for moderate persistent asthma. It is not yet possible to predict which patients respond best to leukotriene modifiers, although there is some evidence that patients with aspirin-sensitive asthma do well, as predicted by studies showing increased cysteinyl leukotriene production in these patients. It is possible that genetic polymorphisms in the 5-lipoxygenase or LTC4 synthase pathways or in cys-LT1 receptors might predict better responders in the future. Antileukotrienes also have modest efficacy in allergic rhinitis.

In general, the LTD4 receptor antagonists are well tolerated and do not appear to have serious class-specific effects. An idiopathic syndrome similar to the Churg-Strauss syndrome, with marked circulating eosinophilia, heart failure, and associated eosinophilic vasculitis, has been reported in a small number of patients treated with zafirlukast and montelukast. The majority of these patients had been receiving high-dose ICS or oral corticosteroids and were able to reduce the dose as a consequence of the LTD4 receptor antagonists. It is unclear whether the increased reports are due to increased

case findings among patients with asthma prescribed a new drug or whether the syndrome is related to corticosteroid dose reduction or an idiosyncratic effect of leukotriene modifiers in general. Whatever the cause, it appears to be a rare syndrome, with an estimated incidence of fewer than 1 case per 15,000 to 20,000 patient-years of treatment.60

Reports of adverse neuropsychiatric events have caused the manufacturers of the leukotriene inhibitors to revise their labeling. However, evidence for causality of suicidal thoughts and suicide is lacking.64 Reports of fatal hepatic failure associated with zafirlukast have prompted a warning for patients to be made aware of signs and symptoms of hepatic dysfunction.2

Zileuton can be administered twice daily as controlled release tablets.2 Efficacy data is more limited, liver function monitoring is recommended, and drug interactions are reported with warfarin and theophylline.

Anti-IgE (Omalizumab)

Omalizumab is a recombinant anti-IgE antibody approved for the treatment of allergic asthma not well controlled on oral corticosteroids or ICSx.65 Omalizumab is a composite of 95% human and 5% antihuman murine IgE sequences. Omalizumab binds to the Fc portion of the IgE antibody preventing the binding of IgE to its high-affinity receptor (FcεRI) on mast cells and basophils. The decreased binding of IgE on the surface of mast cells leads to a decrease in the release of mediators in response to allergen exposure. Omalizumab also decreases FcεRI expression on basophils and airway submucosal mast cells over 8 to 12 weeks.65

Omalizumab is administered subcutaneously and has a slow absorption rate; peak serum concentration is achieved in 3 to 14 days.65 It is eliminated primarily through the reticuloendothelial system and has an elimination half-life of 17 to 22 days; serum free IgE levels return to baseline in about 3 weeks.65 It should be administered under medical observation with drugs for treating anaphylaxis available.

The dosage of omalizumab is determined by the patient’s baseline total serum IgE level (international units per milliliter) and body weight (kilograms).65 Doses range from 150 to 375 mg and are given at either 2- or 4-week intervals. No further adjustments for variations in total serum IgE are required, and patients receive a consistent dose for the duration of treatment.65 Omalizumab is approved for patients greater than 12 years with allergic asthma.65 Clinical trials in 5- to 12-year-olds are ongoing. Due to its significant cost, it is only indicated as step 5 or 6 care for patients who have allergies and severe persistent asthma that are inadequately controlled with the combination of high dose ICS/LABA and at risk for severe exacerbations.7,66 It is the only adjunctive therapy that has demonstrated improved outcomes in patients uncontrolled on ICS/LABA and has allowed oral corticosteroid reduction in a number of studies.2,65 Omalizumab therapy is associated with a 0.2% rate of anaphylaxis prompting an FDA warning that patients should remain in the healthcare provider’s office for a reasonable period of time past the injection as 70% of reactions occur within 2 hours. In addition, patients should be counseled on the signs and symptoms of anaphylaxis because some reactions have occurred up to 24 hours following an injection.2,65

Low-dose methotrexate (15 mg/wk) used for inflammatory diseases, psoriatic and rheumatoid arthritis, and polymyositis has been used to reduce the systemic corticosteroid dose in patients with severe steroid-dependent asthma.67 A meta-analysis of all studies determined that there was insufficient evidence to support its use, particularly in light of the risk for severe side effects.67 Low-dose weekly methotrexate is associated with hepatotoxicity and pulmonary fibrosis.67 The NAEPP has concluded that it should not be used in persistent asthma.2

A number of the drugs with antiinflammatory or immunomodulatory activity such as hydroxychloroquine, dapsone, gold, intravenous gamma-globulin, cyclosporine, and colchicine have been studied in severe corticosteroid-dependent asthma with mixed and limited results.2,68 Routine use is not recommended.2

FUTURE THERAPIES

Agents that are now in development for asthma focus on the treatment of allergic inflammation.69 Examples include inhibitors of eosinophilic inflammation, drugs that may inhibit allergen presentation, and inhibitors of Th2 cells. Multiple cytokines have been implicated in allergic inflammation, and several possible inhibiting approaches are being explored. These range from drugs that inhibit cytokine synthesis (cyclosporin A and tacrolimus), humanized blocking antibodies to cytokines or their receptors, soluble receptors to mop up secreted cytokines, receptor antagonists, and drugs that block the signal-transduction pathways activated by cytokines.69 Unfortunately specific anticytokine therapy against IL-5 and IL-4 have been disappointing to date.69

A FDA has approved Asthmatx Inc.’s Alair Bronchial Thermoplasty System to treat severe asthma in adult patients. This is the first nondrug treatment for asthma. The Alair treatment (3 sessions of 30 minutes each) is performed via a bronchoscope that is inserted into the lungs. A tip of a small catheter then expands to deliver thermal energy to reduce the presence of airway smooth muscle that narrows the airways.70

PHARMACOECONOMIC CONSIDERATIONS

Of the estimated $19.7 billion cost of asthma in the United States in 2004, direct medical expenditure accounted for $14.7 billion of the total, with emergency care (ED and in-patient hospital care) reaching $4.7 billion.7 A cost-of-illness approach takes in all measurable costs; both indirect costs or costs to society and direct medical costs are considered.7,72 Using this approach, indirect costs such as lost work and death accounted for 25% of total expenditures per patient. Although prescription drugs were the largest single direct medical expenditure at $6.7 billion,7 an increase in these costs secondary to improved patient adherence could significantly reduce other costs due to missed school days and lost productivity secondary to asthma morbidity and mortality.

The medication cost increase over the past years resulted from an increase in prescribed medications, as well as an increase in unit cost per medication. Asthma severity affects cost of care as studies from health-maintenance organizations suggest that up to 45% of the cost of asthma is accrued by 10% of the patients, primarily as a result of emergency care.72

Numerous studies have demonstrated the cost-effectiveness of patient education programs for asthma, particularly those providing guided self-management.7 Several studies have reported positive results from pharmacist interventions reducing overall cost of care.2 Similar studies have demonstrated the cost-effectiveness of specialist care compared with generalist care. However, the results of these trials may be confounded by changes in prescribing as part of the

■ MISCELLANEOUS THERAPIES (IMMUNOMODULATORS)

The following therapies have been loosely categorized by the NAEPP with omalizumab as immunomodulators because they either affect the immune system or have antiinflammatory properties. Many have been used experimentally in severe persistent uncontrolled asthma for years to try to avoid or lower oral corticosteroid dosages.

The following therapies have been loosely categorized by the NAEPP with omalizumab as immunomodulators because they either affect the immune system or have antiinflammatory properties. Many have been used experimentally in severe persistent uncontrolled asthma for years to try to avoid or lower oral corticosteroid dosages.
The potential for chronic use of inhaled $\beta_2$-agonists to worsen asthma has been a concern for more than 30 years. Large multicenter, double-blind, placebo-controlled trials with both mild and moderate persistent asthma have not shown that regular administration with short-acting inhaled $\beta_2$-agonists worsened asthma. However, studies that have genotyped patients at the $\beta$-receptor suggest that homozygous Arg-16 patients (who make up about 16% of the population) are predisposed to worsening asthma with regular administration as measured by lower morning PEFs. This phenomenon does not appear to occur with as-needed therapy with short-acting $\beta_2$-agonists. Regular treatment with LABAs does not produce similar effects. The Arg-16 patients still respond acutely to the $\beta_2$-agonists without diminished response. Since the regular use of short-acting inhaled $\beta_2$-agonists does not improve control of symptoms, they should be used only for relief of symptoms. The LABAs should be used only in combination with ICSs where the risk of severe life-threatening exacerbations has not been demonstrated.

EVALUATION OF ASTHMA CONTROL

Control of asthma is defined as reducing both impairment and risk domains. The stepwise approach to therapy should be used to achieve and maintain this control. The steps of care appropriate to the three age ranges of asthma have been outlined in Figure 33–8. Depending on the severity of the patient’s asthma, compromises from the ideal control are made, and the best possible outcome balancing disease control and possible adverse effects from the drugs is attempted. Regular follow-up contact is essential (at 1–6 month intervals, depending on control). A step-down in therapy can be considered, if well-controlled status has been achieved for at least 3 months.

Components of control classification include symptoms, nighttime awakenings, interference with normal activities, pulmonary function, quality of life, exacerbations, medication adherence, treatment-related adverse effects, and satisfaction with care. The categories of well controlled, not well controlled, and very poorly controlled are recommended. Validated questionnaires such as the Asthma Therapy Assessment Questionnaire (ATAQ), the Asthma Control Questionnaire (ACQ), and the Asthma Control Test (ACT) can be regularly administered. The NAEPP minimally recommends spirometric tests at initial assessment, after treatment is initiated, and then every 1 to 2 years. In moderate to severe persistent asthma, PEF monitoring is recommended. PEF monitoring should also be considered in patients who are poor symptom perceivers or those with a history of severe exacerbations. Patients should also be asked about exercise tolerance. All patients on inhaled drugs should have their inhalation delivery technique evaluated periodically—monthly initially and then every 3 to 6 months, before step-up in therapy, adherence, environmental control, and comorbid conditions should be reviewed.

Following initiation of antiinflammatory therapy or an increase in dosage, most patients should begin experiencing a decrease in symptoms in 1 to 2 weeks and achieve maximum symptomatic improvement within 4 to 8 weeks. The use of higher ICS doses or more potent agents may accelerate the process. Improvement in FEV$_1$ and PEF should follow a similar time frame; however, a decrease in BHR, as measured by morning PEF, PEF variability, and exercise tolerance, may take longer and improve over 1 to 3 months. Patients should be informed that following a viral respiratory infection, they may experience decreased exercise tolerance for up to 4 weeks.

Initial visits with the patient should focus on the patient’s concerns, expectations, and goals of treatment. Basic education should focus on asthma as a chronic lung disease, the types of medications, and how they are to be used. Inhaler technique is taught, as is when to seek medical advice. Written action plans should be provided. Either peak flow-based or symptom-based self-monitoring can be effective, if taught and followed correctly. The first follow-up visit should be in 2 to 6 weeks, to evaluate control. At that time, the educational messages of the first visit should be repeated, as well as review of the patient’s current medications, adherence, and any difficulties related to the therapy.

CONCLUSION

Asthma is a complicated disease with a multitude of clinical presentations. The exact defect in asthma has not been defined, and it may be that asthma is a common presentation of a heterogeneous group of diseases. Asthma is defined and characterized by excessive reactivity of the bronchial tree to a wide variety of noxious stimuli. The reaction is characterized by bronchospasm, excessive mucus production, and inflammation. The central role of inflammation in inducing and maintaining BHR is now becoming widely appreciated. The goal of asthma therapy is to normalize, as much as possible, the patient’s life and prevent chronic irreversible lung changes. Drugs are the mainstay of asthma management. The goal of drug therapy is to use the minimum amount of medications possible to completely control the disease. In persistent asthma, therapy should be aimed at bronchospasm and inflammation in order to produce the best results. Patients should be followed and monitored diligently for toxicities. Although death from asthma is an uncommon event, the most common cause of death is under assessment of the severity of obstruction either by the patient or by the clinician; the next common cause is undertreatment. A cornerstone of any therapy is education and the realization that most asthma deaths are avoidable.

VHC: valved holding chamber
VIP: vasoactive intestinal peptide

REFERENCES

Chronic obstructive pulmonary disease (COPD) is a common lung disease characterized by airflow limitation that is not fully reversible and is both chronic and progressive. COPD is preventable and treatable and causes significant extra-pulmonary effects that contribute to disease severity in a subset of patients. The prevalence and mortality of COPD have increased substantially over the past two decades. Currently, COPD is the fourth leading cause of death in the United States. By 2020, it is estimated that COPD will rank fifth in burden of disease and third as a cause of death throughout the world.

There has been a renewed interest in research and in improving clinical management recommendations for patients with COPD in recent years. Although national guidelines for management have been available for over two decades, questions were raised concerning their quality and supporting evidence. In order to standardize the care of patients with COPD and present evidence-based recommendations, the National Heart, Lung, and Blood Institute (NHLBI) and the World Health Organization (WHO) launched the Global Initiative for Chronic Obstructive Lung Disease (GOLD) in 2001. This report has been updated most recently in 2009, and a full revision is expected in 2011.

The role of inhaled corticosteroid therapy in COPD is controversial. International guidelines suggest that patients with severe COPD and frequent exacerbations may benefit from inhaled corticosteroids.

Acute exacerbations of COPD have a significant impact on disease progression and mortality. Treatment of acute exacerbations includes intensification of bronchodilator therapy and a short course of systemic corticosteroids.

Antimicrobial therapy should be used during acute exacerbations of COPD if the patient exhibits at least two of the following: increased dyspnea, increased sputum volume, and increased sputum purulence.

Chronic obstructive pulmonary disease (COPD) is differentiated from asthma in that the airflow limitation that is present is not fully reversible. In a subset of patients, it is fixed with minimal improvement in response to a bronchodilator or with optimal treatment. However, the natural course of the disease is quite variable among patients. The chronic and progressive nature of COPD is associated with an abnormal inflammatory response of the lungs to noxious particles or gases. Nonetheless, COPD is preventable and treatable. In recent years, there has been an increased appreciation for the impact of the systemic response of the lungs to noxious particles or gases.

Nonetheless, certain bronchodilators represent the mainstay of drug therapy for COPD. Pharmacotherapy is used to relieve patient symptoms and improve quality of life. Guidelines recommend short-acting bronchodilators as initial therapy for patients with mild disease. Smoking cessation is the only management strategy proven to slow progression of COPD.

Oxygen therapy has been shown to reduce mortality in selected patients with COPD. Oxygen therapy is indicated for patients with a resting PaO2 of less than 55 mm Hg or a PaO2 of less than 60 mm Hg and evidence of right-sided heart failure, polycythemia, or impaired neurologic function.

Bronchodilators represent the mainstay of drug therapy for COPD. Pharmacotherapy is used to relieve patient symptoms and improve quality of life. Guidelines recommend short-acting bronchodilators as initial therapy for patients with mild or intermittent symptoms.

For the patient who experiences chronic symptoms, long-acting bronchodilators are appropriate. Either a β2-agonist or an anticholinergic offers significant benefits. Combining long-acting bronchodilators is recommended if necessary, despite limited data.
consequences of chronic inflammatory diseases, including COPD, and for the impact of comorbidities in individual patients that can complicate COPD management.

Until recently, clinicians and researchers have exhibited a nihilistic attitude toward the value of treatments for COPD. This was based on the paucity of effective therapies, the destructive nature of the condition, and the fact that the common etiology is cigarette smoking, a modifiable health risk. There is now a renewed interest in evaluating the value of treatments and prevention based on the availability of new therapeutic options for pharmacotherapy and guidelines based on evidence. The international guidelines emphasize the terms preventable and treatable to support a positive approach to managing the patient with COPD. Support is also reflected in the availability of research funding to improve understanding about this disease and its management. This includes NHLBI funding of Specialized Centers of Clinically Oriented Research (SCCOR) programs in COPD that have an objective to promote multidisciplinary research on clinically relevant questions enabling basic science findings to be more rapidly applied to clinical problems.

The term chronic obstructive pulmonary disease has historically been used to describe various pulmonary diseases with a fixed component of airflow limitation. The two principal conditions are chronic bronchitis and emphysema. Chronic bronchitis is associated with chronic or recurrent excessive mucus secretion into the bronchial tree with cough that is present on most days for at least 3 months of the year for at least 2 consecutive years in a patient in whom other causes of chronic cough have been excluded. While chronic bronchitis is defined in clinical terms, emphysema is defined in terms of anatomic pathology. Emphysema historically was defined on histologic examination at autopsy. Because this histologic definition is of limited clinical value, emphysema also has been defined as abnormal permanent enlargement of the airspaces distal to the terminal bronchioles accompanied by destruction of their walls yet without obvious fibrosis.

Differentiating COPD as either chronic bronchitis or emphysema as descriptive subsets of COPD is no longer considered relevant. This is based on the observation that the majority of COPD is caused by a common risk factor (cigarette smoking) and most patients exhibit features of both chronic bronchitis and emphysema. Currently, emphasis is placed on the pathophysiologic features of small airways disease and parenchymal destruction as contributors to chronic airflow limitation. Most patients with COPD demonstrate features of both chronic bronchitis and emphysema. Chronic inflammation affects the integrity of the airways and causes damage and destruction of the parenchymal structures. The underlying problem is persistent exposure to noxious particles or gases that sustain the inflammatory response. The airways of both the lung and the parenchyma are susceptible to inflammation, and the result is the chronic airflow limitation that characterizes COPD (see Fig. 34–1).

### EPIDEMIOLOGY

The true prevalence of COPD is likely underreported in the United States. Data from the National Health Interview Survey in 2001 indicate that 12.1 million people over age 25 years have COPD. Over 9 million of these individuals have chronic bronchitis; the remaining number have emphysema or a combination of both diseases. According to national surveys, the true prevalence of people with symptoms of chronic airflow obstruction may exceed 24 million. The burden may be even greater because more than one-third of adults in the United States reported respiratory complaints compatible with symptomatic COPD in some surveys.

COPD is the fourth leading cause of death in the United States, exceeded only by cancer, heart disease, and cerebrovascular accidents. In 2005, COPD accounted for 126,005 deaths in the United States, representing one in every 20 deaths. Deaths attributed to COPD increased 8% from 2000 to 2005. It is the only leading cause of death to increase over the last 30 years and is projected to be the third leading cause by 2020. Overall, the mortality rate is higher in males; however, the female death rate has doubled over the last 25 years, and the number of female deaths exceeded male deaths in each year since 2000. The mortality rate is higher in whites compared with blacks.

Cigarette smoking is the primary cause of COPD and, although the prevalence of cigarette smoking has declined compared with 1965, approximately 25% of individuals in the United States currently smoke. The trend of increasing COPD mortality likely reflects the long latency period between smoking exposure and complications associated with COPD.

The mortality of COPD is significant; however, morbidity associated with the disease also has a significant impact on patients, their families, and the healthcare system. COPD represents the second leading cause of disability in the United States. In the last 20 years, COPD has been responsible for nearly 50 million hospital visits nationwide. In recent years, a diagnosis of COPD accounts for over 15 million physician office visits, 1.5 million emergency room visits, and 700,000 hospitalizations annually. A survey by the American Lung Association revealed that among COPD patients, 51% reported that their condition limits their ability to work, 70% were limited in normal physical activity, 56% were limited in performing household chores, and 50% reported that sleep was affected adversely.

The economic impact of COPD continues to increase as well. It was estimated at $23 billion in 2000 and rose to $37.2 billion in 2004, including $20.9 billion in direct costs and $16.3 billion in indirect morbidity and mortality costs. By 2020, COPD will be the fifth most burdensome disease, as measured by disability-adjusted life years lost due to illness. The cost of care for COPD patients is high compared with patients without the disease. There is a relationship among the severity of COPD, resources consumed, and the costs of care.

### ETIOLOGY

Cigarette smoking is the most common risk factor and accounts for 85% to 90% of cases of COPD. Components of tobacco smoke activate inflammatory cells, which produce and release the inflammatory mediators characteristic of COPD. Smokers are
TABLE 34-1  Risk Factors for Development of Chronic Obstructive Pulmonary Disease (COPD)

</tbody>
</table>

Inheritance is sometimes described as autosomal codominant by some researchers, because heterozygotes can also have decreased concentrations of AAT enzyme as well. The consequences of AAT deficiency are discussed in the following section as protease-antiprotease imbalance. True AAT deficiency accounts for less than 1% of COPD cases.

AAT is a 42 kDa plasma protein that is synthesized in hepatocytes. A primary role of AAT is to protect cells, especially those in the lung, from destruction by elastase released by neutrophils. In fact, AAT may be responsible for 90% of the inhibition of this destructive enzyme. In individuals with the most common allele (M), plasma levels of AAT are approximately 20 to 50 μmol (100 to 350 mg/dL). The protective effect of AAT in the lungs is significantly diminished when plasma levels are less than 11 μmol (80 mg/dL). AAT is an acute-phase reactant, and the serum concentration can be quite variable.

Several types of AAT deficiency have been identified and are due to mutations in the AAT gene. Two main gene variants, S and Z, have been identified. Patients who are homozygous with the S variant, AAT levels are at least 60% of those of normal individuals. These patients usually do not have an increased risk of COPD compared with normal individuals. Patients with homozygous Z deficiency (ZZ), represent 95% of clinical cases and have AAT levels that are 10% of those of normal individuals, while patients with heterozygous Z variant (SZ) have levels closer to 40% of those of normal individuals. Homozygous Z patients have a higher risk of developing COPD compared with heterozygous Z patients. A history of cigarette smoking increases this risk. A small number of patients have a null phenotype and are at high risk for developing emphysema because they produce virtually no AAT.

Patients with AAT deficiency develop COPD at an early age (20 to 50 years) primarily owing to an accelerated decline in lung function. Compared with an average annual decline in forced expiratory volume in 1 second (FEV1) of 25 mL/year in healthy nonsmokers, patients with homozygous Z deficiency have been reported to have declines of 54 mL/year for nonsmokers and 108 mL/year for current smokers. Effective diagnosis is dependent on clinical suspicion, diagnostic testing of serum concentrations, and genotype confirmation. Patients developing COPD at an early age or those with a strong family history of COPD should be screened for AAT deficiency. If the concentration is low, genotype testing (DNA) should be performed.

Other genes have been implicated with increased risk of developing COPD, including chromosome 2q, transforming growth factor β1, microsomal epoxide hydrolase 1, and tumor necrosis factor α. However, there are no definite conclusions about an association other than AAT. One genetic factor that may reduce the risk of developing COPD is a polymorphism in the gene encoding for matrix metalloproteinase 12 (MMP12). A cohort of smokers with the polymorphism exhibited a lower risk for developing COPD (0.63).

Two additional host factors that may influence the risk of COPD include airway hyperresponsiveness and lung growth. Individuals with airway hyperresponsiveness to various inhaled particles may have an accelerated decline in lung function compared with those without airway hyperresponsiveness. Additionally, individuals who do not attain maximal lung growth owing to low birth weight, prematurity at birth, or childhood illnesses may be at risk for COPD in the future.

PATHOPHYSIOLOGY

COPD is characterized by chronic inflammatory changes that lead to destructive changes and the development of chronic airflow limitation. The inflammatory process is widespread and not only
Involves the airways but also extends to the pulmonary vasculature and lung parenchyma. The inflammation of COPD is often referred to as *neutrophilic* in nature, but macrophages and CD8+ lymphocytes also play major roles. The inflammatory cells release a variety of chemical mediators, of which tumor necrosis factor α (TNF-α), interleukin 8 (IL-8), and leukotriene B4 (LTB4) play major roles. The actions of these cells and mediators are complementary and redundant, leading to the widespread destructive changes. The stimulus for activation of inflammatory cells and mediators is an exposure to noxious particles and gas through inhalation. The most common etiologic factor is exposure to environmental tobacco smoke, although other chronic inhalational exposures can lead to similar inflammatory changes.

Other processes that have been proposed to play a major role in the pathogenesis of COPD include oxidative stress and an imbalance between aggressive and protective defense systems in the lungs (proteinases and antiproteinases). These processes may be the result of ongoing inflammation or occur as a result of environmental pressures and exposures (Fig. 34–2).

An altered interaction between oxidants and antioxidants present in the airways is responsible for the increased oxidative stress present in COPD. Increases in markers (e.g., hydrogen peroxide and nitric oxide) of oxidants are seen in the epithelial lining fluid. The increased oxidants generated by cigarette smoke react with and damage various proteins and lipids, leading to cell and tissue damage. Oxidants also promote inflammation directly and exacerbate the protease-antiprotease imbalance by inhibiting antiprotease activity.

The consequences of an imbalance between proteinases and antiproteinases in the lungs were described over 40 years ago when the hereditary deficiency of the protective antiproteinase AAT was discovered to result in an increased risk of developing emphysema prematurely. This enzyme (AAT) is responsible for inhibiting several protease enzymes, including neutrophil elastase. In the presence of unopposed activity, elastase attacks elastin, a major component of alveolar walls.

In the inherited form of emphysema, there is an absolute deficiency of AAT. In cigarette smoking-associated emphysema, the imbalance is likely associated with increased protease activity or reduced activity of antiproteases. Activated inflammatory cells release several proteinases other than AAT, including cathepsins and metalloproteinases (MMPs). In addition, oxidative stress reduces antiprotease (or protective) activity.

It is helpful to differentiate inflammation occurring in COPD from that present in asthma because the response to antiinflammatory therapy differs. The inflammatory cells that predominate differ between the two conditions, with neutrophils playing a major role in COPD and eosinophils and mast cells in asthma. Mediators of inflammation also differ with LTB4, IL-8, and TNF-α predominating in COPD, compared with LTD4, IL-4, and IL-5 among the numerous mediators modulating inflammation in asthma. Characteristics of inflammation for the two diseases are summarized in Table 34–2.

Pathologic changes of COPD are widespread, affecting large and small airways, lung parenchyma, and the pulmonary vasculature. An inflammatory exudate is often present that leads to an increase in the number and size of goblet cells and mucus glands. Mucus secretion is increased, and ciliary motility is impaired. There is also a thickening of smooth muscle and connective tissue in the airways. Inflammation is present in central and peripheral airways. The chronic inflammation results in a repeated injury and repair process that leads to scarring and fibrosis. Diffuse airway narrowing is present and is more prominent in smaller peripheral airways. The decrease in FEV1 is attributed to the presence of inflammation in the airways, while the blood gas abnormalities result from impaired gas transfer due to parenchymal damage.

Parenchymal changes affect the gas-exchanging units of the lungs, including the alveoli and pulmonary capillaries. The distribution of destructive changes varies depending on the etiology. Most commonly, smoking-related disease results in centrilobular emphysema that primarily affects respiratory bronchioles. Panlobular emphysema is seen in AAT deficiency and extends to the alveolar ducts and sacs.

The vascular changes of COPD include a thickening of pulmonary vessels and often are present early in the disease. Increased pulmonary pressures early in the disease are due to hypoxic vasoconstriction of pulmonary arteries. If persistent, the presence of chronic inflammation may lead to endothelial dysfunction of the pulmonary arteries. Later, structural changes lead to an increase in pulmonary pressures, especially during exercise. In severe COPD, secondary pulmonary hypertension leads to the development of right-sided heart failure.
Mucous hypersecretion is present early in the course of the disease and is associated with an increased number and size of mucus-producing cells. The presence of chronic inflammation perpetuates the process, although the resulting airflow obstruction and chronic airflow limitation may be reversible or irreversible. The various causes of airflow obstruction are summarized in Table 34-3.

Recently, there has been interest in the role of thoracic overinflation as it relates to the pathophysiology of COPD. Chronic airflow obstruction leads to air trapping, which results in thoracic hyperinflation that can be detected on chest radiograph. This problem results in several dynamic changes in the chest, including flattening of diaphragmatic muscles. Under normal circumstances, the diaphragms are dome-shaped muscles tethered at the base of the lungs. When the diaphragm contracts, the muscle becomes shorter and flatter, which creates the negative inspiratory force through which air flows into the lung during inspiration. In the presence of thoracic hyperinflation, the diaphragmatic muscle is placed at a disadvantage and is a less efficient muscle of ventilation. The increased work required by diaphragmatic contractions predisposes the patient to muscle fatigue, especially during periods of exacerbations.

The other consequence of thoracic hyperinflation is a change in lung volumes. For patients with COPD who exhibit thoracic hyperinflation, there is an increase in the functional residual capacity (FRC), which is the amount of air left in the lung after exhalation at rest. Therefore, these patients are breathing at higher lung volumes, which perturbs gas exchange. In addition, the increased FRC limits the inspiratory reserve capacity, which is the amount of air that the patient can inhale to fill the lungs. The increased FRC also limits the duration of inhalation time, and this has been associated with an increase in dyspnea complaints by patients. Drug therapy for COPD, especially bronchodilators, can reduce thoracic hyperinflation by reducing airflow obstruction. This may partially explain the improvement in symptoms reported by patients with COPD despite minimal improvements in lung function with drug therapy.

Airflow limitation is assessed through spirometry, which represents the “gold standard” for diagnosing and monitoring COPD. The hallmark of COPD is a reduction in the ratio of FEV₁ to forced vital capacity (FVC) to less than 70%. The FEV₁ generally is reduced, except in very mild disease, and the rate of FEV₁ decline is greater in COPD patients compared with normal subjects.

The impact of the numerous pathologic changes in the lung perturbs the normal gas-exchange and protective functions of the lung. Ultimately, these are exhibited through the common symptoms of COPD, including dyspnea and a chronic cough productive of sputum. As the disease progresses, abnormalities in gas exchange lead to hypoxemia and/or hypercapnia, although there often is not a strong relationship between pulmonary function and arterial blood gas (ABG) results.

Significant changes in ABGs usually are not present until the FEV₁ is less than 1 L. In these patients, hypoxemia and hypercapnia can become chronic problems. Initially, when hypoxemia is present, it usually is associated with exercise. However, as the disease progresses, hypoxemia at rest develops. Patients with severe COPD can have a low arterial oxygen tension (Pao₂ = 45 to 60 mm Hg) and an elevated arterial carbon dioxide tension (Paco₂ = 50 to 60 mm Hg). The hypoxemia is attributed to hypoventilation (V) of lung tissue relative to perfusion (Q) of the area. This low V/Q ratio will progress over a period of several years, resulting in a consistent decline in the Pao₂. Some COPD patients lose the ability to increase the rate or depth of respiration in response to persistent hypoxemia. Although this is not completely understood, the decreased ventilatory drive may be due to abnormal peripheral or central respiratory receptor responses. This relative hypoventilation subsequently leads to hypercapnia. In this case, the central respiratory response to a chronically increased Paco₂ can be blunted. These changes in Pao₂ and Paco₂ are subtle and progress over a period of many years. As a result, the pH usually is nearly normal because the kidneys compensate by retaining bicarbonate. If acute respiratory distress develops, such as might be seen in pneumonia or a COPD exacerbation with impending respiratory failure, the Paco₂ may rise sharply, and the patient presents with an uncompensated respiratory acidosis.

The consequences of long-standing COPD and chronic hypoxemia include the development of secondary pulmonary hypertension that progresses slowly if appropriate treatment of COPD is not initiated. Pulmonary hypertension is the most common cardiovascular complication of COPD and can result in cor pulmonale, or right-sided heart failure.

The risks of cor pulmonale include venous stasis with the potential for thrombosis and pulmonary embolism. Another important systemic consequence of COPD is a loss of skeletal muscle mass and general decline in the overall health status.

While airway inflammation is prominent for patients with COPD, there is also evidence of systemic inflammation. A consequence is widespread skeletal muscle dysfunction, especially in the leg muscles involved with ambulation. The systemic manifestations can have devastating effects on overall health status and comorbidities. These include cardiovascular events associated with ischemia, cachexia, osteoporosis, anemia, and muscle wasting. There is some interest in the role of measuring C-reactive protein as a parameter to assess systemic inflammation and its impact on COPD severity; however, it is premature to recommend this strategy currently.

### Pathophysiology of Exacerbation

The natural history of COPD is characterized by recurrent exacerbations associated with increased symptoms and a decline in overall health status. An exacerbation is defined as a change in the patient’s baseline symptoms (dyspnea, cough, or sputum production) beyond day-to-day variability sufficient to warrant a change in management. Exacerbations have a significant impact on the natural course of COPD and occur more frequently for patients with more severe chronic disease. Because many patients experience chronic symptoms, the diagnosis of an exacerbation is based, in part, on subjective measures and clinical judgment. Repeated exacerbations, especially those requiring hospitalization, are associated with an increased mortality risk.

There are limited data about pathology during exacerbations owing to the nature of the disease and the condition of patients. However, inflammatory mediators including neutrophils and
CLINICAL PRESENTATION

The diagnosis of COPD is made based on the patient’s symptoms, including cough, sputum production, and dyspnea, and a history of exposure to risk factors such as tobacco smoke and occupational exposures. Patients may have these symptoms for several years before dyspnea develops and often will not seek medical attention until dyspnea is significant. A diagnosis of COPD should be considered for any patient, age 40 years or older, with persistent or progressive dyspnea, with chronic cough productive of sputum, and who exhibits an unusual or abnormal decline in activity, especially in the presence of positive cigarette smoke exposure. In addition, the presence of genetic factors, including AAT deficiency, and occupational exposures should be evaluated because approximately 15% of patients with COPD do not have a history of cigarette smoking.

The presence of airflow limitation should be confirmed with spirometry. Spirometry represents a comprehensive assessment of lung volumes and capacities. The hallmark of COPD is an FEV1:FVC ratio of less than 70%, which indicates airway obstruction, and a postbronchodilator FEV1 of less than 80% of predicted confirms the presence of airflow limitation that is not fully reversible.1 There is an increased awareness that the use of a fixed ratio of less than 70% may be problematic because normal aging may affect this result; however, it continues to be the current standard. An improvement in FEV1 of less than 12% following inhalation of a rapid-acting bronchodilator is considered to be evidence of irreversible airflow obstruction. Reversibility of airflow limitation is measured by a bronchodilator challenge, which is described in Table 34–4. The use of peak expiratory flow measurements is not adequate for the diagnosis of COPD owing to low specificity and the high degree of effort dependence; however, a low peak expiratory flow is consistent with COPD. A comprehensive discussion about spirometry can be found in Chapter 33.

Spirometry combined with a physical examination improves the diagnostic accuracy of COPD. Spirometry is also used to determine the severity of the disease, along with an assessment of symptoms and the presence of complications. A primary benefit of spirometry is to identify individuals who might benefit from pharmacotherapy to reduce exacerbations. Currently, the GOLD consensus guidelines suggest a 4-stage classification system (see Table 34–5).

Previously, guidelines have defined patients at risk for COPD who exhibit normal spirometry but experience chronic symptoms of cough or sputum production in the presence of risk factors. However, this category has been removed because there is not a reliable way to determine which patients might progress to COPD. This change was made because of inadequate evidence to identify patients who might progress to stage 1 disease. Patients with all levels of severity of COPD exhibit the hallmark finding of airflow obstruction, i.e., a reduction in the FEV1:FVC ratio to less than 70%. FVC is the total amount of air exhaled after a maximal inhalation. The extent of reduction in FEV1 further defines the patient with mild, moderate, severe, or very severe disease.1

Spirometry is the primary tool in classifying COPD according to severity. The severity of symptoms also impacts the patient dramatically. Often symptoms do not correlate well with the degree of airflow limitation. Two important factors that influence disease severity, survival, and health-related quality of life are body mass index (BMI) and dyspnea. A low BMI is a systemic consequence of chronic COPD, and a BMI of less than 21 kg/m2 is associated with increased mortality.27 Dyspnea is often the most troublesome complaint for the patient with COPD and often is the stimulus for the patient seeking medical attention. Dyspnea can impair exercise performance and functional capacity and is frequently associated with depression and anxiety. Together, these have a significant effect on health-related quality of life.28 As a subjective symptom, dyspnea is often difficult for the clinician to assess. Various tools are available to evaluate the severity of dyspnea. A version of the Medical Research Council (MRC) scale, modified by the ATS, is commonly employed and categorizes dyspnea grades from 0 to 4 (see Table 34–6).28

While a physical examination is appropriate in the diagnosis and assessment of COPD, most patients who present in the milder stages of COPD will have a normal physical examination. In later stages of the disease, when airflow limitation is severe, patients may have cyanosis of mucosal membranes, development of “barrel chest” due to hyperinflation of the lungs, an increased respiratory rate and shallow breathing, and changes in breathing mechanics such as pursing of the lips to help with expiration or use of accessory respiratory muscles.

From reference 2.

**CLINICAL PRESENTATION**

**Symptoms**
- Chronic cough
- Sputum production
- Dyspnea

**Exposure to Risk Factors**
- Tobacco smoke
- α₁-Antitrypsin deficiency
- Occupational hazards

**Physical Examination**
- Cyanosis of mucosal membranes
- Barrel chest
- Increased resting respiratory rate
- Shallow breathing
- Pursed lips during expiration
- Use of accessory respiratory muscles

**Diagnostic Tests**
- Spirometry with reversibility testing
- Radiograph of chest
- Arterial blood gas (not routine)

**FEATURES OF COPD EXACERBATION**

**Symptoms**
- Increased sputum volume
- Acutely worsening dyspnea
- Chest tightness
- Presence of purulent sputum
- Increased need for bronchodilators
- Malaise, fatigue
- Decreased exercise tolerance

**Physical Examination**
- Fever
- Wheezing, decreased breath sounds

**Diagnostic Tests**
- Sputum sample for Gram stain and culture
- Chest radiograph to evaluate for new infiltrates

**PROGNOSIS**

For the patient with COPD, the combination of impaired lung function and recurrent exacerbations promote a clinical scenario characterized by dyspnea, reduced exercise tolerance and physical activity, and deconditioning. These factors lead to disease progression, poor quality of life, possible disability, and premature mortality. COPD is ultimately a fatal disease if it progresses and advanced directives and end-of-life care options are appropriate to consider. The primary causes of death of patients with COPD include respiratory failure, cardiovascular events or diseases, and lung cancer.

The FEV<sub>1</sub> is the most important prognostic indicator for a patient with COPD. The average rate of decline of FEV<sub>1</sub> is the most useful objective measure to assess the course of COPD. The average rate of decline in FEV<sub>1</sub> for healthy, nonsmoking patients owing to age alone is 25 to 30 mL/year. The rate of decline for smokers is steeper, especially for heavy smokers compared with light smokers. The decline in pulmonary function is a steady curvilinear path. The more severely diminished the FEV<sub>1</sub> at diagnosis, the steeper is the rate of decline. Greater numbers of years of smoking and number of cigarettes smoked also correlate with a steeper decline in pulmonary function. Conversely, the rate of decline of blood gases has not been shown to be a useful parameter to assess progression of the disease. Patients with COPD should have spirometry performed at least annually to assess disease progression.

The survival rate of patients with COPD is highly correlated to the initial level of impairment in the FEV<sub>1</sub> and age. Other less important factors include degree of reversibility with bronchodilators, resting pulse, perceived physical disability, diffusing capacity (D<sub>LCO</sub>), cor pulmonale, and blood gas abnormalities. A rapid decline in pulmonary function tests indicates a poor prognosis. Median survival is approximately 10 years when the FEV<sub>1</sub> is 1.4 L, 4 years when the FEV<sub>1</sub> is 1.0 L, and about 2 years when the FEV<sub>1</sub> is 0.5 L.

While ABG measurements are important, they do not carry the prognostic value of pulmonary function tests. Measurement of ABGs is more useful for patients with severe disease and is recommended for all patients with an FEV<sub>1</sub> of less than 40% of predicted or those with signs of respiratory failure or right-sided heart failure.

Asthma is usually differentiated from COPD based on the patient's medical history, risk factors, and improvements on post-bronchodilator spirometry; however, in some cases, asthma patients exhibit COPD-like features and COPD patients exhibit asthma-like features. It is also possible for the two conditions to coexist.

**CLINICAL PRESENTATION OF COPD EXACERBATION**

Because of the subjective nature of defining an exacerbation of COPD, the criteria used among clinicians varies widely; however, most rely on a change in one or more of the following clinical findings: worsening symptoms of dyspnea, increase in sputum volume, or increase in sputum purulence. Acute exacerbations have a significant impact of the economics of treating COPD as well, estimated at 35% to 45% of the total costs of the disease in some settings.

A widely accepted definition of an exacerbation is that it is an event in the natural course of COPD that is characterized by a worsening in baseline dyspnea, cough, and/or sputum that is beyond the normal day-to-day variation, is acute in onset, and may warrant a change in regular medication. With an exacerbation, patients using rapid-acting bronchodilators may report an increase in the frequency of use. Exacerbations are commonly staged as mild, moderate, or severe according to the criteria summarized in Table 34–7.
An important complication of a severe exacerbation is acute respiratory failure. In the emergency department or hospital, an ABG usually is obtained to assess the severity of an exacerbation. The diagnosis of acute respiratory failure in COPD is made based on an acute change in the ABGs. Defining acute respiratory failure as a PaO$_2$ of less than 50 mm Hg or a PaCO$_2$ of greater than 50 mm Hg often may be incorrect and inadequate because these values may not represent a significant change from a patient’s baseline values. A more precise definition is an acute drop in PaO$_2$ of 10 to 15 mm Hg or any acute increase in PaCO$_2$ that decreases the serum pH to 7.3 or less. Additional acute clinical manifestations of respiratory failure include restlessness, confusion, tachycardia, diaphoresis, cyanosis, hypotension, irregular breathing, miosis, and unconsciousness.

PROGNOSIS

COPD exacerbations are associated with significant morbidity and mortality. While mild exacerbations may be managed at home, mortality rates are higher for patients admitted to the hospital. In one study of patients hospitalized with COPD exacerbations, in-hospital mortality was 6% to 8%. Many patients experiencing an exacerbation do not have a return to their baseline clinical status for several weeks, significantly affecting their quality of life. Additionally, as many as half the patients originally hospitalized for an exacerbation are readmitted within 6 months.

It is now evident that acute exacerbations of COPD have a tremendous impact on disease progression and ultimate mortality. For exacerbations requiring hospitalizations, mortality rates range from 22% to 43% after 1 year, and 36% to 49% in 2 years. Unfortunately, most treatments for COPD have not been shown to improve survival or to slow the progressive decline in lung function. However, many therapies do improve pulmonary function and quality of life and reduce exacerbations and duration of hospitalization. Several disease-specific quality-of-life measures are available to assess the overall efficacies of therapies for COPD, including the Chronic Respiratory Questionnaire (CRQ) and the St. George’s Respiratory Questionnaire (SGRQ). These questionnaires measure the impact of various therapies on such disease variables as severity of dyspnea and level of activity. They do not measure impact of therapies on survival. While early studies of COPD therapies focused primarily on improvements in pulmonary function measurements such as FEV$_1$, there is a trend toward greater use of these disease-specific quality-of-life measures to evaluate the benefits of therapy on larger clinical outcomes.

GENERAL APPROACH TO TREATMENT

To be effective, the clinician should address four primary components of management: Assess and monitor the condition, avoidance of or reduced exposure to risk factors, manage stable disease, and treat exacerbations. These components are addressed through a variety of nonpharmacologic and pharmacologic approaches.

NONPHARMACOLOGIC THERAPY

Patients with COPD should receive education about their disease, treatment plans, and strategies to slow progression and prevent complications. Advice and counseling about smoking cessation are essential, if applicable. Because the natural course of the disease leads to respiratory failure, the clinician should address end-of-life decisions and advanced directives prospectively with the patient and family.

Smoking Cessation

Smoking cessation represents the single most important intervention in preventing the development, as well as the progression of COPD. A primary component of COPD management is avoidance of or reduced exposure to risk factors. Exposure to environmental tobacco smoke is a major risk factor, and smoking cessation is the most effective strategy to reduce the risk of developing COPD and to slow or stop disease progression. The cost-effectiveness of smoking-cessation interventions compares favorably with interventions made for other major chronic diseases. The importance of smoking cessation cannot be overemphasized. Smoking cessation leads to decreased symptomatology and slows the rate of decline of pulmonary function even after significant abnormalities in pulmonary function tests have been detected (FEV$_1$/FVC <60%). As confirmed by the Lung Health Study, smoking cessation is the only intervention proven at this time to affect long-term decline in...
FEV, and slow the progression of COPD. In this 5-year prospective trial, smokers with early COPD were randomly assigned to one of three groups: smoking-cessation intervention plus inhaled ipratropium 3 times a day, smoking-cessation intervention alone, or no intervention. During an 11-year follow-up, the rate of decline in FEV among subjects who continued to smoke was more than twice the rate in sustained quitters. Smokers who underwent smoking-cessation intervention had fewer respiratory symptoms and a smaller annual decline in FEV compared with smokers who had no intervention. However, this study also demonstrated the difficulty in achieving and sustaining successful smoking cessation.

Tobacco cessation has mortality benefits beyond those related to COPD. A follow-up analysis of the Lung Health Study data conducted more than 14 years later demonstrated an 18% reduction in all-cause mortality in patients that received the intervention compared with usual care. Intervention patients had lower death rates due to coronary artery disease (the leading cause of mortality), cardiovascular diseases, and lung cancer, although all categories did not reach clinical significance.

Every clinician has a responsibility to assist smokers in smoking-cessation efforts. A clinical practice guideline for treating tobacco dependence from the U.S. Public Health Service (PHS) was updated in 2008. The major findings and recommendations of that report are summarized in Table 34-9. An earlier report from the Surgeon General in 2004 on the health consequences of smoking broadened the scope of the detrimental effects of cigarette smoking, indicating that "Smoking harms nearly every organ of the body, causing many diseases and reducing the health of smokers in general."14

### TABLE 34-9  Key Guideline Recommendations Regarding Tobacco Use and Dependence

| Tobacco dependence is a chronic disease that often requires repeated intervention and multiple attempts to quit. Effective treatments are available that can significantly improve rates of long-term abstinence. Clinicians and healthcare delivery systems should consistently identify and document tobacco use status and treat every tobacco user. Tobacco-dependence treatments are effective over a broad range of populations. Clinicians should encourage every patient willing to make a quit attempt to use counseling treatments and medications recommended in the guideline. Brief tobacco-dependence treatments are effective. Clinicians should offer every patient who uses tobacco at least these brief treatments. Individual, group, and telephone counseling are effective, and their effectiveness increases with treatment intensity. Practical counseling (problem-solving and/or skills training) and social support are especially effective and should be employed as a part of treatment. There are numerous effective medications for tobacco dependence, and clinicians should encourage their use by patients during a quit attempt, except when medically contraindicated or with populations in which the evidence of effectiveness is insufficient (pregnancy, smokeless tobacco users, light smokers, and adolescents). Seven first-line medications (5 nicotine and 2 non-nicotine) consistently increase long-term abstinence rates. Clinicians should also consider the use of combinations as identified in the guideline. Counseling and medication are effective when used by themselves for treating tobacco dependence. The combination of the two is more effective than either alone. Patients should be encouraged to use both counseling and medication. Telephone quitline counseling is effective for diverse populations and offers the advantage of broad reach. Clinicians should ensure patient access to quitlines and promote quitline use. For a tobacco user who is currently unwilling to make a quit attempt, clinicians should use motivational treatments that have been shown to be effective in increasing future quit attempts. Tobacco-dependence treatments are both clinically effective and highly cost-effective relative to interventions for other clinical disorders. Providing coverage for these treatments increases quit rates. Insurers and purchasers should ensure that all insurance plans include the counseling and medications identified as effective in the guideline as covered benefits. | |

All clinicians should take an active role in assisting patients with tobacco dependence in order to reduce the burden on the individual, his or her family, and the healthcare system. It is estimated that over 75% of smokers want to quit and that one-third have made a serious effort. Yet complete and permanent tobacco cessation is difficult. Counseling that is provided by clinicians is associated with greater success rates than self-initiated efforts.32

The PHS guidelines recommend that clinicians take a comprehensive approach to smoking-cessation counseling. Advice should be given to smokers even if they have no symptoms of smoking-related disease or if they are receiving care for reasons unrelated to smoking. Clinicians should be persistent in their efforts because relapse is common among smokers owing to the chronic nature of dependence. Brief interventions (3 minutes) of counseling are proven effective. However, it must be recognized that the patient must be ready to stop smoking because there are several stages of decision-making. Based on this, a 5-step intervention program is proposed (Table 34-10).

There is strong evidence to support the use of pharmacotherapy to assist in smoking cessation. In fact, it should be offered to most patients as part of a cessation attempt. In general, available therapies will double the effectiveness of a cessation effort. Agents that are considered first line are listed in Table 34-11. The usual duration of therapy is 8 to 12 weeks, although some individuals may require longer courses of treatment. Precautions to consider before using bupropion include a history of seizures or an eating disorder. Nicotine-replacement therapies are contraindicated for patients with unstable coronary artery disease, active peptic ulcers, or recent myocardial infarction or stroke. Nicotine patch, bupropion, and the combination of bupropion and the nicotine patch were compared with placebo in a controlled trial. The treatment groups that received bupropion had higher rates of smoking cessation than the groups that received placebo or the nicotine patch. The addition of the nicotine patch to bupropion slightly improved the smoking-cessation rate compared with bupropion monotherapy. Recently, a new agent became available to assist in tobacco cessation attempts. Varenicline is a nicotine acetylcholine receptor partial agonist that has shown benefit in tobacco cessation. Varenicline relieves physical withdrawal symptoms and reduces the rewarding properties of nicotine. Nausea and headache are the most frequent complaints associated with varenicline. Currently, varenicline has not been studied in combination with other tobacco-cessation therapies. Second-line agents are less effective or associated with greater side effects; however, they may be useful in selected clinical situations. These therapies include clonidine and nortriptyline, a tricyclic antidepressant.

Behavioral modification techniques or other forms of psychotherapy also may be helpful in assisting in smoking cessation. Programs that address the many issues associated with smoking (i.e., learned behaviors, environmental influences, and chemical dependence) using a team approach are more likely to be successful. The role of alternative-medicine therapies in smoking cessation is controversial. Hypnosis may aid in improving abstinence rates when added to a smoking-cessation program but appears to give little benefit when used alone. Acupuncture has not been shown to contribute to smoking cessation and is not recommended.2
Other Environmental Triggers

Although cigarette smoke represents the overwhelming majority of risk for developing COPD, exposure to other environmental toxins also confer risks. Exposures to occupational dusts and fumes have been implicated as a cause of COPD in 19% of smokers and 31% of nonsmokers with COPD in the United States. In the case of known environmental hazards, primary prevention is appropriate. Policies to limit airborne exposures in the workplace and outdoors, as well as education efforts of workers and policy makers are recommended.

Pulmonary Rehabilitation

Exercise training is beneficial in the treatment of COPD to improve exercise tolerance and to reduce symptoms of dyspnea and fatigue. Pulmonary rehabilitation programs are an integral component in the management of COPD and should include exercise training along with smoking cessation, breathing exercises, optimal medical treatment, psychosocial support, and health education. Pulmonary rehabilitation has no direct effect on lung function or gas exchange. Instead, it optimizes other body systems so that the impact of poor lung function is minimized. Exercise training reduces the CNS response to dyspnea, ameliorates anxiety and depression, reduces thoracic hyperinflation, and improves skeletal muscle function. High-intensity training (70% maximal workload) is possible even in advanced COPD patients, and the level of intensity improves peripheral muscle and ventilatory function. Studies have demonstrated that pulmonary rehabilitation with exercise 3 to 7 times per week can produce long-term improvement in activities of daily living, quality of life, exercise tolerance, and dyspnea for patients with moderate to severe COPD. Improvements in dyspnea can be achieved without concomitant improvements in spirometry. Programs using less intensive exercise regimens (2 times per week) have not been shown to be of benefit.

Immunizations

Vaccines can be considered as pharmacologic agents; however, their role is described here in reducing risk factors for COPD exacerbations. Because influenza is a common complication in COPD that can lead to exacerbations and respiratory failure, an annual vaccination with the inactivated intramuscular influenza vaccine is recommended. Immunization against influenza can reduce serious illness and death by 50% in COPD patients. Influenza vaccine should be administered in the fall of each year (October and November) during regular medical visits or at vaccination clinics. There are few contraindications to influenza vaccine except for a patient with a serious allergy to eggs. An oral antiinfluenza agent (oseltamivir) can be considered for patients with COPD during an outbreak for patients who have not been immunized; however, this therapy is less effective and causes more side effects. The multivalent pneumococcal vaccine, usually administered 1 time, is widely recommended for people from 2 to 64 years of age who have chronic lung disease and for all people older than 65 years. Thus, COPD patients at any age are candidates for vaccination. Although evidence for the benefit of the pneumococcal vaccine in COPD is not strong, the argument for continued use is that the current vaccine provides coverage for 85% of pneumococcal strains causing invasive disease and the increasing rate of resistance of pneumococcus to selected antibiotics. Currently, administering the vaccine remains the standard of practice and is recommended by the Centers for Disease Control and Prevention and the American Lung Association. Repeated vaccination with the 23-valent product is not recommended for patients aged 2 to 64 years with chronic lung disease; however, revaccination is recommended for patients over 65 years of age if the first vaccination was more than 5 years earlier and the patient was younger than age 65. The GOLD guidelines recommend pneumococcal vaccine for all COPD patients 65 years and older and for patients less than 65 years only if the FEV₁ is less than 40% predicted. In 2009, the CDC broadened their recommendations for the pneumococcal polysaccharide vaccine to include all persons ages 18 and over who smoke based on a higher risk of pneumococcal infection in these patients.

Long-Term Oxygen Therapy

The use of supplemental oxygen therapy increases survival in COPD patients with chronic hypoxemia. Although long-term oxygen has been used for many years for patients with advanced COPD, it was not until 1980 that data became available documenting its benefits. At that time, the Nocturnal Oxygen Therapy Trial Group published its data comparing nocturnal oxygen therapy (NOT), 12 hours per day, with continuous oxygen therapy (COT), average of 20 hours per day. Among patients who were followed for at least 12 months, the results revealed a mortality rate in the NOT group that was nearly double that of the COT group (51% vs 26%). Statistical estimates of the COT group suggest that COT may have added 3.25 years to a COPD patient’s life. Additional data from the Nocturnal Oxygen Therapy Trial Group revealed that COT patients had fewer (but statistically insignificant) hospitalizations, improved quality of life and neuropsychological function, reduced hematocrit, and decreased pulmonary vascular resistance.

The decline in mortality with oxygen therapy was further substantiated in 1981 in a study by the British Medical Research Council that compared 15 h/day of oxygen versus no supplemental oxygen in COPD patients. Patients receiving oxygen therapy for at least part of the day had lower rates of mortality than those not receiving oxygen. Long-term oxygen therapy provides even more benefit in terms of survival after at least 5 years of use, and it improves the quality of life of these patients by increasing walking distance and neuropsychological condition and reducing time spent in the hospital. Before patients are considered for long-term oxygen therapy, they should be stabilized in the outpatient setting, and pharmacotherapy should be optimized. Once this is accomplished, long-term oxygen therapy should be instituted if either of two conditions exists:

1. A resting Pao₂ of less than 55 mm Hg
2. Evidence of right-sided heart failure, polycythemia, or impaired neuropsychiatric function with a Pao₂ of less than 60 mm Hg

1. A resting Pao₂ of less than 55 mm Hg
2. Evidence of right-sided heart failure, polycythemia, or impaired neuropsychiatric function with a Pao₂ of less than 60 mm Hg
The most practical means of administering long-term oxygen is with the nasal cannula, at 1 to 2 L/min, which provides 24% to 28% oxygen. The goal is to raise the PaO₂ above 60 mm Hg. Patient education about flow rates and avoidance of flames (i.e., smoking) is of the utmost importance.

There are three different ways to deliver oxygen, including (1) in liquid reservoirs, (2) compressed into a cylinder, and (3) via an oxygen concentrator. Although conventional liquid oxygen and compressed oxygen are quite bulky, smaller, portable tanks are available to permit greater patient mobility. Oxygen concentrator devices separate nitrogen from room air and concentrate oxygen. These are the most convenient and the least expensive method of oxygen delivery. Oxygen-conservation devices are available that allow oxygen to flow only during inspiration, making the supply last longer. These may be particularly useful to prolong the oxygen supply for mobile patients using portable cylinders. However, the devices are bulky and subject to failure.

Adjunctive Therapies
In addition to supplemental oxygen, adjunctive therapies to consider as part of a pulmonary rehabilitation program are psychoeducational care and nutritional support. Psychoeducational care (such as relaxation) has been associated with improvement in the functioning and well-being of adults with COPD. The role of nutritional support for patients with COPD is controversial. Several studies have shown an association among malnutrition, low BMI, and impaired pulmonary status among patients with COPD. However, a metaanalysis suggests that the effect of nutritional support on outcomes in COPD is small and not associated with improved anthropometric measures, lung function, or functional exercise capacity.

Pharmacologic Therapy
Results from numerous recent clinical trials have improved insight and understanding about the respective roles of various medications used in chronic COPD management; yet, some controversies still exist related to both effectiveness and safety. In contrast to the survival benefit conferred by supplemental oxygen therapy, there is no medication available for the treatment of COPD that has been shown to modify the progressive decline in lung function or prolong survival. There is limited evidence that chronic treatment with long-acting inhaled β₂-agonists, inhaled corticosteroids, or the combination can reduce the rate of decline in spirometry in a subset of patients with more severe disease. Currently, the primary goal of pharmacotherapy is to control patient symptoms and reduce complications, including the frequency and severity of exacerbations and improving the overall health status and exercise tolerance of the patient.

International guidelines recommend a stepwise approach to the use of pharmacotherapy based on disease severity, which is determined by the extent of airflow limitation and degree of symptoms. The impact of recurrent exacerbations on accelerating disease progression is increasingly recognized as an important factor to be considered. The primary goals of pharmacotherapy are to control symptoms (including dyspnea), reduce exacerbations, and improve exercise tolerance and health status. Currently, there is inadequate evidence to support the use of more aggressive pharmacotherapy early in the course of disease because of the lack of a disease modifying benefit. Because of the progressive nature of COPD, pharmacotherapy tends to be chronic and cumulative and step down approaches in stable patients are not successful. Patients exhibit variable responses to available therapies and the treatment approach should be individualized.

Pharmacotherapy of COPD typically involves the use of inhaled medications, requiring patient knowledge, understanding, and skills using the various inhalation devices. Several delivery devices are available (e.g., metered-dose inhalers, dry powder inhalers, nebulizers, and ancillary devices such as holding chambers), and the instructions about proper use vary. Comorbidities that are common for patients with COPD, including physical and mental conditions, can have a significant effect on the patient’s ability to use the devices. Periodic and frequent reinforcement and observation by the clinician is required for the patient’s benefit.

Pharmacotherapy focuses on the use of bronchodilators to control symptoms. Bronchodilators relax bronchial smooth muscle, improve lung emptying, reduce thoracic hyperinflation at rest and during exercise, and improve exercise tolerance. These effects can be seen in the absence of objective improvements on spirometry. There are several classes of bronchodilators to choose from, and no single class has been proven to provide superior benefit over other available agents. The initial and subsequent choice of medications should be based on the specific clinical situation and patient characteristics. Medications can be used as needed or on a scheduled basis depending on the clinical situation, and additional therapies should be added in a stepwise manner depending on the response and severity of disease. Considerations should be given to individual patient response, tolerability, adherence, and economic factors. A stepwise approach to the management of COPD has been proposed based on the stage of disease severity (Fig. 34–3).

According to the guidelines, patients with intermittent symptoms should be treated with short-acting bronchodilators. When symptoms become more persistent, long-acting bronchodilators should be initiated. For patients with an FEV₁ less than 50% and who experience frequent exacerbations, inhaled corticosteroids should be considered. Short-acting bronchodilators relieve symptoms and increase exercise tolerance. Long-acting bronchodilators relieve symptoms, reduce exacerbation frequency, and improve quality of life and health status. Patients have a variety of choices in using inhalational therapies, including metered dose inhalers (MDI), dry powder inhalers (DPI), or nebulizers. There is not a clear advantage of one delivery method over another, and it is recommended that patient-specific factors and preferences should be considered in selecting the device.

Bronchodilators
Bronchodilator classes available for the treatment of COPD include β₂-agonists, anticholinergics, and methylxanthines. There is no clear benefit to one agent or class over others, although inhaled therapy generally is preferred. In general, it can be more difficult for patients with COPD to use inhalation devices effectively compared with other populations owing to advanced age and the presence of other comorbidities. Clinicians should advise, counsel, and observe patient technique with the devices frequently and consistently.

Bronchodilators generally work by reducing the tone of airway smooth muscle (relaxation), thus minimizing airflow limitation. For patients with COPD, the clinical benefits of bronchodilators include increased exercise capacity, decreased air trapping in the lungs, and relief of symptoms such as dyspnea. However, use of bronchodilators may not be associated with significant improvements in pulmonary function measurements such as FEV₁. In clinical studies, regular use of a long-acting inhaled bronchodilator (LABA or Anticholinergic) or ipratropium are associated with improved health status. Regular use of tiotropium also reduces exacerbation rates. In general, side effects of bronchodilator medications are related to their pharmacologic effects and are dose dependent. Because COPD patients are older and more likely to have comorbid
conditions, the risk for side effects and drug interactions is higher compared with patients with asthma.

**Short-Acting Bronchodilators** The initial therapy for COPD patients who experience symptoms intermittently are short-acting bronchodilators. Among these agents, the choices are a short-acting beta, agonist or an anticholinergic. Either class of agents has a relatively rapid onset of action, relieves symptoms, and improves exercise tolerance and lung function. In general, both classes are equally effective.

**Short-Acting Sympathomimetics (β₂-Agonists)** A number of sympathomimetic agents are available in the United States. They vary in selectivity, route of administration, and duration of action. In COPD management, sympathomimetic agents with β₂-selectivity, or β₂-agonists, should be used as bronchodilators. β₂-Agonists cause bronchodilation by stimulating the enzyme adenylyl cyclase to increase the formation of cyclic adenosine monophosphate (cAMP). cAMP is responsible for mediating relaxation of bronchial smooth muscle, leading to bronchodilation. In addition, they may improve mucociliary clearance. Although shorter-acting and less selective β-agonists are still used widely (e.g., metaproterenol, isoetharine, isoproterenol, and epinephrine), they should not be used owing to their shorter duration of action and increased cardiostimulatory effects. Short-acting, selective β₂-agonists such as albuterol, levalbuterol, and pirbuterol are preferred for therapy.

Sympathomimetics are available in inhaled, oral, and parenteral dosage forms. The preferred route of administration is by inhalation. The use of oral and parenteral β-agonists in COPD is discouraged because they are no more effective than a properly used metered-dose inhaler (MDI) or dry-powder inhaler (DPI), and the incidence of systemic adverse effects such as tachycardia and hand tremor is greater. Administration of β₂-agonists in the outpatient and emergency room settings via inhalers (MDIs or DPIs) is at least as effective as nebulizer utilization therapy and usually favored for reasons of cost and convenience. Chapter 33 includes a complete description of the devices used for delivering aerosolized medication and a comparison β₂-agonist therapies.

Albuterol is the most frequently used β₂-agonist. It is available as an oral and inhaled preparation. Albuterol is a racemic mixture of (R)-albuterol, which is responsible for the bronchodilator effect, and (S)-albuterol, which has no therapeutic effect. (S)-Albuterol is considered by some clinicians to be inert, whereas others believe that it may be implicated in worsening airway inflammation and antagonizing the response to (R)-albuterol. Levalbuterol is a single-isomer formulation of (R)-albuterol. A retrospective evaluation of levalbuterol versus albuterol use for patients with asthma and COPD concluded that levalbuterol offered significant advantages over albuterol for hospitalized patients. Other clinicians feel that there are no significant differences between the products and that the use of levalbuterol is not justified owing to its higher acquisition cost. The effects of a single dose of levalbuterol have been compared with those of albuterol and ipratropium plus albuterol for patients with COPD. No significant differences in pulmonary function improvements or adverse effects were noted.

In COPD patients, β₂-agonists exert a rapid onset of effect, although the response generally is less than that seen in asthma. Short-acting inhaled β₂-agonists cause only a small improvement in FEV₁ acutely but may improve respiratory symptoms and exercise tolerance despite the small improvement in spirometric measurements. Patients with COPD can use quick-onset β₂-agonists as needed for relief of symptoms or on a scheduled basis to prevent or reduce symptoms. The duration of action of short-acting β₂-agonists is 4 to 6 hours.

Inhaled β₂-agonists are generally well tolerated. They can cause sinus tachycardia and rhythm disturbances in predisposed patients, but these are rarely reported. Skeletal muscle tremors can occur initially but subside as tolerance develops.

**Short-Acting Anticholinergics** When given by inhalation, anticholinergics such as ipratropium or atropine produce bronchodilation by competitively inhibiting cholinergic receptors in bronchial smooth muscle. This activity blocks acetylcholine, with the net effect being a reduction in cyclic guanosine monophosphate (cGMP), which normally acts to constrict bronchial smooth muscle. Muscarinic receptors on airway smooth muscle include M₁, M₂, and
M₂ subtypes. Activation of M₁ and M₄ receptors by acetylcholine results in bronchoconstriction; however, activation of M₂ receptors inhibits further acetylcholine release.

Ipratropium is the primary short-acting anticholinergic agent used for COPD in the United States. Atropine has a tertiary structure and is absorbed readily across the oral and respiratory mucosa, whereas ipratropium has a quaternary structure that is absorbed poorly. The lack of systemic absorption of ipratropium greatly diminishes the anticholinergic side effects such as blurred vision, urinary retention, nausea, and tachycardia associated with atropine. Ipratropium bromide is available as an MDI and a solution for inhalation. The MDI was recently reformulated with an HFA propellant and delivers 17 mcg per puff. Ipratropium is also available as an MDI in combination with albuterol and as a solution for nebulization at 200 mcg/mL. It provides a peak effect in 1.5 to 2 hours and has a duration of effect of 4 to 6 hours. Ipratropium has a slower onset of action and a more prolonged bronchodilator effect compared with standard β₂-agonists. Because of the slower onset of effect (15 to 20 minutes compared with 5 minutes for albuterol), it may be less suitable for as-needed use; however, it is often prescribed in that manner. The role of inhaled anticholinergics in COPD is well established.

However, results from the Lung Health Study showed that treatment with ipratropium did not affect the progressive decline in lung function. Studies comparing ipratropium with inhaled β₂-agonists have generally reported similar improvements in pulmonary function. Others report a modest benefit with ipratropium, including a lower incidence of side effects such as tachycardia.

Although the recommended dose of ipratropium is 2 puffs four times a day, there is evidence for a dose-response, so the dose can be titrated upward often to 24 puffs a day. Ipratropium has been shown to increase maximum exercise performance in stable COPD patients with doses of 8 to 12 puffs prior to exercise but not with doses of 4 puffs or less. During sleep, ipratropium also has been shown to improve arterial oxygen saturation and sleep quality. Ipratropium is well tolerated. The most frequent patient complaints are dry mouth, nausea, and an occasional metallic taste.

Clinicians differ about preference in choosing the initial short-acting bronchodilator therapy for the patient with COPD. Both a short-acting β₂-agonist and ipratropium represent reasonable choices for initial therapy.

### Long-Acting Bronchodilators

For patients with moderate to severe COPD who experience symptoms on a regular and consistent basis, or in whom short-acting therapies do not provide adequate relief, long-acting bronchodilator therapies are the recommended treatment. Long-acting inhaled bronchodilator therapy can be administered as an inhaled β₂-agonist (LABA) or an anticholinergic. Long-acting, inhaled bronchodilator therapy is more convenient and effective, compared with short-acting agents, for patients with chronic symptoms. There are superior outcomes in lung function as measured by spirometry, symptoms including dyspnea, and, importantly, reductions in exacerbation frequency and improved quality of life.

### Long-Acting Inhaled β₂-Agonists (LABAs)

LABAs offer the convenience and benefit of a long duration of action for patients with persistent symptoms. Each of the currently available agents, salmeterol, formoterol, and arformoterol is dosed every 12 hours and provides sustained bronchodilation. Arformoterol and formoterol has an onset of action similar to albuterol (less than 5 minutes), whereas salmeterol has a slower onset (15 to 20 minutes); however, neither agent is recommended for acute relief of symptoms. There is no dose titration for any of these agents; the starting dose is the effective and recommended dose for all patients. The clinical benefits of long-acting inhaled β₂-agonists compared with short-acting therapies include similar or superior improvements in lung function and symptoms, as well as reduced exacerbation rates in some studies.

The use of the long-acting agents should be considered for patients with frequent and persistent symptoms. When patients require short-acting β₂-agonists on a scheduled basis, LABAs are more convenient based on dosing frequency but are also more expensive. Salmeterol and formoterol are available in dry powder inhalation devices, and formoterol and arformoterol as solutions for nebulization. An ultra-long-acting agent, indacaterol, which requires once daily dosing is in phase 3 and 4 clinical trials in 2009.

LABAs are also useful to reduce nocturnal symptoms and improve quality of life. When compared with short-acting bronchodilators or theophylline, both salmeterol and formoterol improve lung function, symptoms, exacerbation frequency, and quality of life. These benefits are apparent even for patients with poorly reversible lung function and are related to improvements in inspiratory capacity. Both salmeterol and formoterol have been compared with ipratropium. In separate studies, each agent improved FEV₁ compared with ipratropium and, in addition, the LABA was more effective for other selected outcomes (e.g., prolonged time to exacerbation for salmeterol while formoterol reduced symptoms and rescue inhaler use).

### Long-Acting Anticholinergics

Tiotropium bromide, a long-acting quaternary anticholinergic agent, has been available in the United States since 2004. This agent blocks the effects of acetylcholine by binding to muscarinic receptors in airway smooth muscle and mucus glands, blocking the cholinergic effects of bronchoconstriction and mucus secretion. Tiotropium is more selective than ipratropium at blocking important muscarinic receptors. Tiotropium dissociates slowly from M₃ and M₅ receptors, allowing prolonged bronchodilation. The dissociation from M₁ receptors is much faster, allowing inhibition of acetylcholine release. Binding studies of tiotropium in the human lung show that it is approximately 10-fold more potent than ipratropium and protects against cholinergic bronchoconstriction for greater than 24 hours.

When inhaled, tiotropium is minimally absorbed into the systemic circulation and results in bronchodilation within 30 minutes, with a peak effect in 3 hours. Bronchodilation persists for at least 24 hours, allowing for a once daily dosing. There is no titration of tiotropium dose; a regimen of 18 mcg inhaled once daily is recommended for all patients. In the United States, it is delivered via the HandiHaler, a single-load, dry-powder, breath-actuated device. Because it acts locally, tiotropium is well tolerated, with the most common complaint being a dry mouth. Other anticholinergic side effects that are reported include constipation, urinary retention, tachycardia, blurred vision, and precipitation of narrow-angle glaucoma symptoms.

The benefits of tiotropium have been evaluated in numerous trials of patients with COPD. Similar to long-acting β₂-agonists, tiotropium improves lung function and dyspnea, exacerbation frequency, and health-related quality of life. In this study, tiotropium improved FEV₁ by an average of 12% to 22% compared with placebo. The tolerance that is demonstrated with chronic use of β₂-agonists does not occur with tiotropium therapy, as improvements in lung function are sustained with long-term therapy.

There is a large body of evidence supporting the use of tiotropium as a long acting bronchodilator for COPD patients. Benefits have been demonstrated compared with placebo and to ipratropium. Tiotropium therapy is associated with a decreased risk of exacerbations compared with placebo or ipratropium, and equal or superior efficacy compared with LABAs in various studies.

As a long-acting bronchodilator, tiotropium is an option to consider in addition to long-acting inhaled β₂-agonists for COPD.
management. Once-daily tiotropium has been compared with twice-daily salmeterol in two placebo-controlled trials of 6 months duration. Tiotropium reduced asthma exacerbations and hospital admissions and improved quality of life, whereas both active treatments improved lung function and reduced dyspnea. In another 6-month randomized, controlled trial of patients with COPD, patients were randomized to receive either tiotropium once daily by DPI, salmeterol twice daily by MDI, or placebo. Patients receiving tiotropium had greater improvements in trough FEV₁ and dyspnea scores than those receiving salmeterol. Patients also were more likely to have improvements in quality-of-life indicators with tiotropium than with salmeterol. However, no differences in frequency of exacerbations were noted among the three groups.

The most notable study involving the use of tiotropium in recent years for patients with COPD was the Understanding Potential Long-term Impacts on Function with Tiotropium(UPLIFT) trial. This was a randomized, double-blind study of 4 years duration. A total of 5,993 subjects received either tiotropium 18 mcg daily inhaled via a HandiHaler device or a matching placebo. All other COPD therapies were allowed except for other anticholinergic therapies (e.g., ipratropium). The mean postbronchodilator FEV₁ among subjects was 1.32 L, and the primary outcome was the rate of decline in FEV₁ on spirometry. The results showed that tiotropium treatment resulted in prebronchodilator FEV₁ improvement of 87 to 103 mL, and postbronchodilator improvement of 47 to 65 mL, both of which were statistically significant. However, the rate of decline in the mean FEV₁ result was not statistically significant between the groups. Tiotropium-treated subjects benefited from treatment as reflected in improved quality-of-life scores, reduced exacerbation rates, fewer hospitalizations, and instances of respiratory failure. Tiotropium was associated with a lower overall risk of mortality, including deaths from respiratory and cardiac causes.

The safety of tiotropium documented in the UPLIFT trial is reassuring. Recently, retrospective analysis have reported an increased risk of cardiovascular events associated with ipratropium and tiotropium use. However, the UPLIFT study, which was a prospective trial over 4 years, did not report an increased cardiovascular risk associated with tiotropium use.

**Combination Anticholinergics and β₂-Agonists**

Combination regimens of bronchodilators are used often in the treatment of COPD, especially as the disease progresses and symptoms worsen over time. Combining bronchodilators with different mechanisms of action allows the lowest possible effective doses to be used and reduces potential adverse effects from individual agents. Combinations of both short- and long-acting β₂-agonists with ipratropium have been shown to provide added symptomatic relief and improvements in pulmonary function. A combination of albuterol and ipratropium (Combivent) is available as an MDI in the United States for chronic maintenance therapy of COPD. This product offers the obvious convenience of two classes of bronchodilators in a single inhaler.

Although clinical practice guidelines recommend that combinations of long-acting bronchodilators are appropriate for patients who do not receive adequate benefit from a single agent, data to support the use of these combinations have been lacking. These approaches have been the focus of more recent research. Future combination inhalation products may contain long-acting β₂-agonists with tiotropium to reduce the need for frequent dosing. In a preliminary single-dose study, the combination of tiotropium and formoterol resulted in a faster and greater improvement in FEV₁ compared with either treatment alone. In another trial, 95 subjects received either tiotropium 18 mcg or tiotropium plus formoterol 12 mcg either once or twice daily. All patients received each therapy for 2 weeks each in an open label, crossover design. Both combination regimens improved lung function and reduced rescue therapy use compared with tiotropium alone.

**Methylxanthines**

Methylxanthines, including theophylline and aminophylline, have been available for the treatment of COPD for at least five decades and at one time were considered first-line therapy. However, with the availability of long-acting inhaled β₂-agonists and inhaled anticholinergics, the role of methylxanthine therapy is significantly limited. Inhaled bronchodilator therapy is preferred for COPD. Because of the risk for drug interactions and the significant intrapatient and interpatient variability in dosage requirements, theophylline therapy generally is considered for patients who are intolerant or unable to use an inhaled bronchodilator. Theophylline is still an alternative to commonly used inhaled therapies partially due to the potential for multiple mechanisms (bronchodilation and anti-inflammatory) and the possible benefit that systemic administration may exert on peripheral airways.

The methylxanthines may produce bronchodilation through numerous mechanisms, including (1) inhibition of phosphodiesterase, thereby increasing cAMP levels, (2) inhibition of calcium influx into smooth muscle, (3) prostaglandin antagonism, (4) stimulation of endogenous catecholamines, (5) adenosine receptor antagonism, and (6) inhibition of release of mediators from mast cells and leukocytes.

Chronic theophylline use for patients with COPD has been shown to exert improvements in lung function, including vital capacity (VC), FEV₁, minute ventilation, and gas exchange. Subjectively, theophylline has been shown to reduce dyspnea, increase exercise tolerance, and improve respiratory drive in COPD patients. Other nonpulmonary effects of theophylline that may contribute to improved overall functional capacity for patients with COPD include improved cardiac function and decreased pulmonary artery pressure.

Although theophylline is available in a variety of oral dosage forms, sustained-release preparations are most appropriate for the long-term management of COPD. These products have the advantages of improving patient compliance and achieving more consistent serum concentrations over rapid-release theophylline and aminophylline preparations. However, caution must be used in switching from one sustained-release preparation to another because there are considerable variations in sustained-release characteristics. Aside from intravenous aminophylline, there is no need to use any of the various salts forms of theophylline.

Regular use of methylxanthines has not been shown to have either a beneficial or a detrimental effect on the progression of COPD. However, methylxanthines may be added to the treatment plan of patients who have not achieved an optimal clinical response to ipratropium and an inhaled β₂-agonist. Studies suggest that adding theophylline to a combination of albuterol and ipratropium provides added benefit for stable COPD patients, supporting the hypothesis that there is a synergistic bronchodilator effect. The efficacy of combination therapy with salmeterol and theophylline for patients with COPD was reported to improve pulmonary function and reduce dyspnea better than either treatment alone. Combination treatment also was associated with a reduced number of exacerbations only when compared with the theophylline group, suggesting that the salmeterol component was responsible for this beneficial effect.

As is the case with other bronchodilator therapy, parameters other than objective measurements, such as FEV₁, should be monitored to assess efficacy of theophylline in COPD. Subjective parameters, such as perceived improvements in symptoms of dyspnea and exercise tolerance, become increasingly important in assessing the acceptability of methylxanthines for COPD patients. Although objective improvement may be minimal, patients may
experience an improvement in clinical symptoms, and thus benefit to the individual may be meaningful.

The role of theophylline in COPD is as maintenance therapy in the nonacutely ill patient. Therapy can be initiated at 200 mg twice daily and titrated upward every 3 to 5 days to the target dose. Most patients required daily doses of 400 to 900 mg. Dosage adjustments generally should be made based on serum concentration results. Traditionally, the therapeutic range of theophylline was identified as 10 to 20 mcg/mL; however, because of the frequency of dose-related side effects and the relatively minor benefit of higher concentrations, a more conservative therapeutic range of 8 to 15 mcg/mL often is targeted. This is especially preferable for the elderly. When concentrations are measured, trough measurements are most appropriate.

Once a dose is established, serum concentrations should be monitored once or twice a year unless the patient’s disease worsens. Medications that interfere with theophylline metabolism are added to therapy, or toxicity is suspected. The most common side effects of theophylline therapy are related to the gastrointestinal system, the cardiovascular system, and the central nervous system. Side effects are dose-related; however, there is overlap in side effects between the therapeutic and toxic ranges. Minor side effects include dyspepsia, nausea, vomiting, diarrhea, headache, dizziness, and tachycardia. More serious toxicities, especially at toxic concentrations, include arrhythmias and seizures.

Factors that decrease theophylline clearance and lead to reduced maintenance-dose requirements include advanced age, bacterial or viral pneumonia, left or right ventricular failure, liver dysfunction, hypoxemia from acute decompensation, and use of drugs such as cimetidine, macrolides, and fluoroquinolone antibiotics. Factors that may enhance theophylline clearance and result in the need for higher maintenance doses include tobacco and marijuana smoking, hyperthyroidism, and the use of such drugs as phenytoin, phenobarbital, and rifampin.

In summary, there are decades of experience with theophylline and other methylxanthine products in the management of patients with COPD. However, inhalation therapy is currently preferred based on superior efficacy and safety, as well as ease of use by the clinician. Theophylline is a challenging medication to dose, monitor, and manage due to the significant intrapatient and interpatient variability in pharmacokinetics and the potential for drug interactions and toxicities.

Corticosteroids

Corticosteroid therapy has been studied and debated in COPD therapy for half a century; however, owing to the poor risk-to-benefit ratio, chronic systemic corticosteroid therapy should be avoided if possible.1 Because of the potential role of inflammation in the pathogenesis of the disease, clinicians hoped that corticosteroids would be promising agents in COPD management. However, their use continues to be debated, especially in the management of stable COPD.

The antiinflammatory mechanisms whereby corticosteroids exert their beneficial effect in COPD include (1) reduction in capillary permeability to decrease mucus, (2) inhibition of release of proteolytic enzymes from leukocytes, and (3) inhibition of prostaglandins. Unfortunately, the clinical benefits of systemic corticosteroid therapy in the chronic management of COPD are often not evident, and the risk of toxicity is extensive and far-reaching. Currently, the appropriate situations to consider corticosteroids in COPD include (1) short-term systemic use for acute exacerbations and (2) inhalation therapy for chronic stable COPD.

The role of oral steroid use in chronic stable COPD patients was evaluated in a metaanalysis over a decade ago.47 Investigators concluded that only a small fraction (10%) of COPD patients treated with steroids showed clinically significant improvement in baseline FEV1 (increase of 20%) compared with those treated with placebo. While a small number of COPD patients are considered responders to oral steroids, many of these patients actually may have an asthmatic, or reversible, component to their disease. The best predictors for response to oral steroids are the presence of eosinophils on sputum examination (≥3%) and a significant response to sympathomimetics on pulmonary function tests.48 Both the presence of eosinophils in sputum and the responsiveness to sympathomimetics suggest an asthmatic component to the disease process and thus may explain the clinical benefit seen with steroids.

Long-term adverse effects associated with systemic corticosteroid therapy include osteoporosis, muscular atrophy, thinning of the skin, development of cataracts, and adrenal suppression and insufficient. The risks associated with long-term steroid therapy are much greater than the clinical benefits. If a decision to treat with long-term systemic corticosteroids is made, the lowest possible effective dose should be given once per day in the morning to minimize the risk of adrenal suppression. If therapy with oral agents is required, an alternate-day schedule should be used.

Previously, a common clinical practice was to administer a short course (2 weeks) of oral corticosteroids as a trial to predict which patients would benefit from chronic oral or inhaled corticosteroids. There is now sufficient evidence suggesting that this practice is not effective in predicting a long-term response to inhaled corticosteroids and should not be recommended.49

The use of chronic inhaled corticosteroid therapy has been of interest for the past decade. Their use has been common despite the lack of firm evidence about significant clinical benefit until recently. Inhaled corticosteroids have an improved risk-to-benefit ratio compared with systemic corticosteroid therapy. Using the model for asthma, it was hoped that the inhalation of potent corticosteroid would result in high local efficacy and limited systemic exposure and toxicity. In the latter part of the 1990s, several large international trials were initiated to evaluate the effect on inhaled corticosteroids in COPD. Unfortunately, the results of these major clinical trials failed to demonstrate any benefit from chronic treatment with inhaled corticosteroids in modifying long-term decline in lung function that is characteristic of COPD. Therefore, the role of inhaled corticosteroids in COPD continues to be debated in the literature, unlike in asthma, where their use is clearly advocated. Much of the debate centers on the appropriate outcome measures in this population of patients.

During the last decade, several studies of inhaled corticosteroids in COPD were designed to detect a benefit on slowing the progressive loss of lung function, but the results were disappointing.101-106 None of the large national or international trials were able to demonstrate a benefit of high-dose inhaled corticosteroid therapy on this primary outcome. However, inhaled corticosteroids have been associated with other important benefits in some patients, including a decrease in exacerbation frequency and improvements in overall health status.102,106,107

Clinicians continue to debate the most appropriate and relevant outcome measure to evaluate in COPD studies. Based on the results of clinical trials, consensus guidelines suggest that inhaled corticosteroid therapy should be considered for symptomatic patients with stage III or IV disease (FEV1 <50%) who experience repeated exacerbations.1,12 These are the patients who demonstrated benefit in clinical trials and in whom a trial of inhaled corticosteroid therapy is warranted. There are also data from epidemiologic studies that suggest that chronic treatment with inhaled corticosteroids is associated with a lower risk of rehospitalization for a broader group of patients with COPD. Thus the debate about the appropriate role for this antiinflammatory therapy continues.

A metaanalysis evaluating randomized clinical trials involving inhaled corticosteroids for patients with COPD indicated that
treatment was associated with a relative risk reduction in exacerbation frequency of 33%. The report indicated that 12 patients would require treatment for 20.8 months to prevent one exacerbation episode. The benefit was evident for patients with moderate to severe COPD.\textsuperscript{108} This metaanalysis did not detect a mortality benefit.

Other investigators have reported a reduction in mortality for patients with COPD who were treated with inhaled corticosteroids. In an epidemiologic study of a Canadian database, patient mortality 3 months to 1 year following a hospitalization for a COPD exacerbation was evaluated for patients who received inhaled corticosteroids in the first 3 months compared with those who did not. For patients over 65 years of age, inhaled corticosteroid therapy reduced mortality by 25%. Much of the mortality reduction was reflected in deaths due to cardiovascular causes. Conversely, patients who received only bronchodilator therapy trended toward higher mortality rates, although not significant.\textsuperscript{109} A pooled analysis of seven large trials also concluded that inhaled corticosteroids reduced all-cause mortality in COPD patients.\textsuperscript{110}

Currently, the recommended role of inhaled corticosteroid therapy is for COPD patients with moderate to severe airflow obstruction (FEV₁ <50% predicted) and who experience frequent exacerbations despite bronchodilator therapy. Repeated exacerbations are described as 3 in 3 years. The initial hope that treatment with inhaled corticosteroids would prevent or slow the progressive decline in FEV₁ remains unproven; however, it is often argued that additional important outcomes for patients with COPD include relief of symptoms, fewer and less severe exacerbations, and improved quality of life.\textsuperscript{111} Inhaled corticosteroids (ICS) do not prolong survival in COPD patients and there is good evidence to suggest that treatment with ICS increases the risk of pneumonia for patients with COPD.\textsuperscript{112–114}

Although a dose-response relationship for ICS has not been demonstrated in COPD, the major clinical trials employed moderate to high doses for treatment. Side effects of ICS are relatively mild compared with the toxicity from systemic therapy. Hoarseness, sore throat, oral candidiasis, and skin bruising have been reported in the clinical trials. Severe side effects, such as adrenal suppression, osteoporosis, and cataract formation, have been reported less frequently than with systemic corticosteroids, but clinicians should monitor patients who are receiving high-dose chronic therapy.\textsuperscript{115,116}

There is evidence supporting a dose relationship between inhaled corticosteroid use and the risk of fractures. In a cohort of over 1,600 subjects with a diagnosis of asthma or COPD (mean age 80 years), the risk of a fracture was 2.53 times higher (CI, 1.65-3.89) in those receiving a mean daily dose of inhaled corticosteroid of 601 mcg or greater.\textsuperscript{117} However, the data are conflicting about this issue. A metaanalysis found no evidence supporting an increased risk of fractures or decreased bone mineral density with chronic inhaled corticosteroid use.\textsuperscript{118} It appears prudent to suggest that, to minimize the risk of fracture, patients should be treated with the lowest effective dose of ICS.\textsuperscript{119} It may also be helpful to recommend adequate intake of calcium and vitamin D and possibly periodic bone mineral density testing.

Combination Therapy: Bronchodilators and Inhaled Corticosteroids

Following the disappointing results of chronic inhaled corticosteroid studies and the progressive decline in lung function, investigators became interested in the combination of potent antiinflammatory therapies and long-acting bronchodilators. Subsequently, several studies have shown an additive benefit with long-acting bronchodilators.\textsuperscript{120–123} In various studies, combination therapy with salmeterol plus fluticasone or formoterol plus budesonide was associated with greater improvements in clinical outcomes such as FEV₁, health status, and frequency of exacerbations compared with ICS or long-acting bronchodilators alone. The availability of combination inhalers (e.g., salmeterol plus fluticasone and budesonide plus formoterol) makes administration of both ICS and long-acting bronchodilators more convenient for patients and decreases the total number of inhalations needed daily. An inhaled corticosteroid combined with a long acting β-agonist is superior to the individual components in reducing exacerbations, improving lung function and overall health status.\textsuperscript{122} Therefore, there is growing evidence that inhaled corticosteroid and long-acting β-agonist combinations improve lung function, as well as reduce symptoms of dyspnea and exacerbation frequency.\textsuperscript{122–124}

The combination of a long-acting β-agonist and inhaled corticosteroid has been compared with the long-acting β-agonist therapy alone. In a study involving nearly 1,000 patients with severe but stable COPD, subjects received either salmeterol 50 mcg/fluticasone 500 mcg twice daily or salmeterol 50 mcg twice daily for 44 weeks. Exacerbation frequency was significantly lower in the combination group (334 vs 464 episodes), which corresponded to a 35% reduction in the annualized rate. The time to the first exacerbation was also delayed with the combination therapy.\textsuperscript{122} One finding of concern reported in this trial was the increased number of pneumonia cases for patients receiving combination therapy compared with salmeterol alone. There were 23 cases reported compared with 7 in the salmeterol group.\textsuperscript{123} An increase in the risk for pneumonia was also reported in the Towards a Revolution in COPD Health (TORCH) study described below.\textsuperscript{122}

The largest prospective study to date is referred to as the Towards a Revolution in COPD Health (TORCH) study.\textsuperscript{122} This trial consisted of 6,112 patients who received one of four treatments for three years. Treatment groups were placebo, salmeterol 50 mcg twice daily, fluticasone 500 mcg twice daily, or the combination of salmeterol and fluticasone in a single inhaler. The primary outcome was death from any cause and secondary outcomes were exacerbation rates, lung function, and health status. None of the active treatments differed significantly from placebo, although the combination of salmeterol and fluticasone trended toward fewer deaths (P = .052). The combination also reduced exacerbation rates, and improved lung function and health status compared with the other treatments. Exacerbation rates were also significantly reduced with combination therapy compared with either single agent alone. Both treatment groups that included fluticasone had higher rates of pneumonia. Although this study did not reflect a mortality benefit, the authors indicated the risk of death was reduced by 17.5% with the combination and that the number needed to treat for 1 year to provide a benefit was 4.

For patients with an FEV₁ of less than 60% predicted, the individual agents and the combination decreased the rate of spirometry decline.\textsuperscript{126}

In a head-to-head trial, a large study comparing a combination of salmeterol and fluticasone to tiotropium alone showed no difference in the exacerbation rates between the groups, although the combination therapy was associated with a higher study completion rate.\textsuperscript{126}

Combinations of Long-Acting Bronchodilators Compared with Long-Acting Bronchodilators Plus Inhaled Corticosteroids

The combination of salmeterol and tiotropium has also been evaluated in a short-term crossover study involving only 22 subjects who received either salmeterol (50 mcg twice daily) plus fluticasone (500 mcg twice daily), fluticasone plus tiotropium (18 mcg once daily), or fluticasone, salmeterol, and tiotropium for 1 week. The triple combination provided a significant benefit of improved lung function compared with either of the dual treatments in subjects with moderate to severe COPD.\textsuperscript{127} The benefit of
pharmacotherapy consists of intensive management involving 449 subjects with moderate to severe COPD. Treatment consisted of either tiotropium, tiotropium plus salmeterol, or tiotropium, salmeterol, and fluticasone.\textsuperscript{128} There was no difference between treatments for the primary outcome of percentage of patients experiencing an exacerbation requiring systemic corticosteroids or antibiotics. The triple-drug regimen improved lung function, quality of life, and reduced hospitalization compared with tiotropium alone, while two-drug therapy did not offer any benefit in lung function improvement or hospitalization rates compared with the single agent. Another small study evaluated the addition of tiotropium for 1 month to a regimen of an inhaled corticosteroid and a long-acting β-agonist.\textsuperscript{129} The addition of tiotropium improved lung function and quality-of-life scores, apparently by improving dynamics of lung capacity (inspiratory capacity). These effects were reversed when tiotropium therapy was discontinued. These data involving combinations of long acting bronchodilators are limited and preliminary. More research is required and should include other outcome parameters including relief of symptoms, exacerbation rates, and quality of life. Larger sample sizes and longer durations will provide insight into the value of combinations.

A retrospective cohort study of 42,090 patients in the Veterans Affairs healthcare system evaluated outcomes for patients with COPD who received tiotropium as part of a COPD regimen compared with a cohort of COPD patients who did not receive the medication. Patients who received tiotropium with ICS plus a long-acting β-agonist exhibited a 40% reduction in mortality compared with patients treated with ICS plus a long-acting β-agonist alone (95% CI of 0.45-0.79). Triple therapy patients also significantly reduced exacerbations and hospitalization rates. However, this same study demonstrated that tiotropium combined with two other medications (various) increased mortality and morbidity risks.\textsuperscript{85}

\textbf{α}-Antitrypsin Replacement Therapy

For patients with inherited AAT deficiency-associated emphysema, treatment focuses on reduction of risk factors such as smoking, symptomatic treatment with bronchodilators, and augmentation therapy with replacement AAT. Based on knowledge about the relationship between serum concentrations of AAT and the risk of developing emphysema, the rationale for augmentation therapy is to maintain serum concentrations above the protective threshold throughout the dosing interval.\textsuperscript{130} Indirect evidence of AAT activity in the interstitium of the lung has been demonstrated by measuring concentrations of the enzyme in epithelial lining fluid obtained during bronchoalveolar lavage. Augmentation therapy consists of weekly infusions of pooled human AAT to maintain AAT plasma levels over 10 micromolar. Much of the data supporting the use of AAT replacement is based on evidence of biochemical efficacy (e.g., administering the product and demonstrating protective serum concentrations of AAT).

Clinical evidence for slowing lung function decline or improving outcomes with augmentation therapy is sparse. Stated challenges to performing randomized clinical trials include the large sample size and long duration of follow-up required, and the expense of conducting such a trial. One observational study followed patients in the National Registry of Severe AAT Deficiency over a period of several years and documented clinical outcomes. In this study, patients who received weekly augmentation therapy with purified AAT had slower declines in FEV₁, and decreased mortality compared with patients who never received augmentation therapy.\textsuperscript{131} However, this was an observational study of patients, not a randomized, placebo-controlled trial, and so direct cause-and-effect relationships cannot be concluded. One randomized, placebo-controlled study of patients with severe AAT deficiency (ZZ phenotype) did show a significant reduction in lung tissue loss and destruction as measured by computed tomographic (CT) scan for patients receiving augmentation therapy.\textsuperscript{132} Other measures of lung function and mortality were not recorded.

The recommended dosing regimen for replacement AAT is 60 mg/kg administered intravenously once a week at a rate of 0.08 mL/kg per minute, adjusted to patient tolerance. It has been estimated that this form of augmentation therapy will cost over $54,000 annually.\textsuperscript{133} In the absence of alternative treatments, it is difficult to assess the cost-effectiveness using conventional criteria. There have been repeated problems with supply of this biologic replacement therapy (derived from pooled blood donors) related to production difficulty and contamination issues. Currently, there are three products available (Prolastin (Bayer), Aralast (Baxter), and Zemaira (ZLB Behring), which should minimize this problem in the future. Drug development research continues in the area of recombinant products and inhalational therapy.

The safety of AAT replacement therapy has been recently evaluated in two large observational studies. In the most recent study, 174 patients (n = 747) reported 720 adverse events, classified as severe in 8.8% of cases and moderate in 72.4% of cases.\textsuperscript{134} Common complaints included headache, dizziness, nausea, dyspnea, and fever. The overall rate of adverse events was low (i.e., two events over 5 years).

\section*{TREATMENT}

\subsection*{COPD Exacerbation}

\textbf{DESIRED OUTCOMES}

The goals of therapy for patients experiencing exacerbations of COPD are (1) prevention of hospitalization or reduction in hospital stay, (2) prevention of acute respiratory failure and death, and (3) resolution of exacerbation symptoms and a return to baseline clinical status and quality of life.\textsuperscript{135} Acute exacerbations can range from mild to severe. Factors that influence the severity, and subsequently the level of care required, include the severity of airflow limitation, presence of comorbidities and the history of previous exacerbations. Table 34–12 includes factors that warrant treatment in the hospital.

Various therapeutic options for exacerbation management are summarized in Table 34–13. Pharmacotherapy consists of intensification of bronchodilator therapy and a short course of systemic corticosteroids. Antimicrobial therapy is indicated in the presence of selected symptoms. Since the frequency and severity of exacerbations are closely related to each patient’s overall health status, all patients should receive optimal chronic treatment, including smoking cessation, appropriate pharmacologic therapy, and preventative therapy such as vaccinations.

\begin{table}[h]
\centering
\caption{Factors Favoring Hospitalization for Treatment of COPD Exacerbation}
\begin{tabular}{|l|}
\hline
Presence of high risk comorbidity (e.g., pneumonia, arrhythmia, CHF, diabetes, renal or hepatic failure) \\
Suboptimal response to outpatient management \\
Marked worsening of dyspnea \\
Inability to eat or sleep due to symptoms \\
Worsening hypoxemia or hypercapnia \\
Mental status changes \\
Lack of home support for care \\
Uncertain diagnosis \\
\hline
\end{tabular}
\end{table}

\textsuperscript{Modified from ATS.}
Compared with treatment with usual care alone, the benefits associated with lower mortality, lower intubation rates, shorter hospital stays, and greater improvements in serum pH in 1 hour are seen with NPPV generally can be attributed to a reduction in the complications that often arise with invasive mechanical ventilation. Not all patients with COPD exacerbations are appropriate candidates for NPPV. Patients with altered mental status may not be able to protect their airway and thus may be at increased risk for aspiration. Patients with severe acidosis (pH <7.25), respiratory arrest, or cardiovascular instability should not be considered for NPPV. Patients failing a trial of NPPV or those considered poor candidates might be considered for intubation and mechanical ventilation.

### Noninvasive Positive-Pressure Ventilation (NPPV)

NPPV provides ventilatory support with oxygen and pressurized airflow using a face or nasal mask with a tight seal but without endotracheal intubation. There have been numerous trials reporting the benefits of NPPV for patients with acute respiratory failure due to COPD exacerbations. In one metaanalysis of eight studies, NPPV was used to achieve a PaO\(_2\) of greater than 60 mm Hg or oxygen saturation of greater than 90%. However, an ABG should be obtained after oxygen initiation to monitor carbon dioxide retention owing to hypoventilation.

### Controlled Oxygen Therapy

Oxygen therapy should be considered for any patient with hypoxemia during an exacerbation. Caution must be used, however, because many patients with COPD rely on mild hypoxemia to trigger their drive to breathe. In normal, healthy individuals, the drive to breathe is triggered by carbon dioxide accumulation. For patients with COPD who retain carbon dioxide as a result of their disease progression, hypoxemia rather than hypercapnia becomes the main trigger for their respiratory drive. Overly aggressive administration of oxygen to patients with chronic hypercapnia may result in respiratory depression and respiratory failure. Oxygen therapy should be used to achieve a PaO\(_2\) of greater than 60 mm Hg or oxygen saturation of greater than 90%. However, an ABG should be obtained after oxygen initiation to monitor carbon dioxide retention owing to hypoventilation.

### Corticosteroids

Until recently, the literature supporting the use of corticosteroids in acute exacerbations of COPD was sparse. However, since 1996, five studies have been performed that document the value of systemic corticosteroids in exacerbations of COPD. The Systemic Corticosteroids in Chronic Obstructive Pulmonary Disease Exacerbations (SCCOPE) trial evaluated three groups of patients hospitalized for exacerbations of COPD. The first group received an 8-week course of corticosteroids given as methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by once-daily oral prednisone (60 mg on days 4 through 7, 40 mg on days 8 through 11, 20 mg on days 12 through 43, 10 mg on days 44 through 50, and 5 mg on days 51 through 57). The second group received a 2-week course given as methylprednisolone 125 mg intravenously every 6 hours for 72 hours, followed by oral prednisone (60 mg on days 5 through 7, 40 mg on days 8 through 11, and 20 mg on days 12 through 15) and placebo on days 16 through 57. The third group received placebo for all 57 days of study. Rates of treatment failure and hospital stay were significantly higher in the placebo group than in either treatment group at 30 and 90 days. Groups randomized to corticosteroid treatment also had a significantly shorter length of hospital stay compared with the placebo group. The 8-week regimen was not found to be superior to the 2-week regimen. Significant treatment benefits were no longer evident at 6 months.

Davies and colleagues evaluated the oral use of corticosteroids in hospitalized patients with acute exacerbations of COPD. Patients received either 30 mg/day oral prednisolone or placebo for 14 days. Patients who were treated with corticosteroids had a significantly more rapid improvement in FEV\(_1\), and a shorter hospital stay than did patients who received placebo. There was no significant difference between groups at 6-week follow-up. In total, results from these trials suggest that patients with acute exacerbations of COPD should receive a short course of intravenous or oral corticosteroids. However, because of the large variability in dosage ranges, the optimal dose and duration of corticosteroid treatment are not known. It appears that short courses (9 to 14 days) are as effective as longer courses and have a lower risk of associated adverse effects owing to less time of exposure. Several trials used high initial doses of steroids before tapering to a lower maintenance dose. Adverse effects such as hyperglycemia, insomnia, and hallucinations may occur at higher doses. Depending on the clinical status of the patient, treatment may be initiated at a
lower dose or tapered more quickly if these effects occur. It appears that a regimen of prednisone 40 mg orally daily (or equivalent) for 10 to 14 days can be effective for most patients. If steroid treatment is continued for greater than 2 weeks, a tapering oral schedule should be employed to avoid hypothalamic-pituitary-adrenal (HPA) axis suppression.

Recent data suggest that ICs may be beneficial for treating COPD exacerbations, although this is not the standard of care. In one study, inhaled budesonide, alone or combined with formoterol, was as effective as oral corticosteroids in treating COPD exacerbations.

Antimicrobial Therapy

It is thought that most acute exacerbations of COPD are caused by viral or bacterial infections. However, as many as 30% of exacerbations are caused by unknown factors. A metaanalysis of nine studies evaluating the effectiveness of antibiotics in treating exacerbations of COPD determined that patients receiving antibiotics had a greater improvement in peak expiratory flow rate than those who did not.

This metaanalysis concluded that antibiotics are of most benefit and should be initiated if at least two of the following three symptoms are present: increased dyspnea, increased sputum volume, and increased sputum purulence. The utility of sputum Gram stain and culture is questionable because some patients have chronic bacterial colonization of the bronchial tree between exacerbations.

The emergence of drug-resistant organisms has mandated that antibiotic regimens be chosen judiciously. Selection of empirical antimicrobial therapy should be based on the most likely organism(s) thought to be responsible for the infection based on the individual patient profile. The most common organisms for any acute exacerbation of COPD are Hemophilus influenzae, Moraxella catarrhalis, Streptococcus pneumoniae, and Hemophilus parainfluenzae. More virulent bacteria may be present for patients with more complicated acute exacerbations of COPD, including drug-resistant pneumococci, β-lactamase-producing H. influenzae and M. catarrhalis, and enteric gram-negative organisms, including Pseudomonas aeruginosa. Table 34–14 summarizes recommended antimicrobial therapy for exacerbations of COPD and the most common organisms based on patient presentation.

Therapy with antibiotics generally should be continued for at least 7 to 10 days. Studies evaluating shorter treatment courses (usually 5 days) with the fluoroquinolones, second- and third-generation cephalosporins, and macrolide antimicrobials have demonstrated comparable efficacy with the longer treatment regimens. If the patient deteriorates or does not improve as anticipated, hospitalization may be necessary, and more aggressive attempts should be made to identify potential pathogens responsible for the exacerbation.

COPD patients are at increased risk for pulmonary embolism during severe exacerbations requiring hospitalizations. An increased awareness of this risk and appropriate preventative measures are warranted.

### COMPLICATIONS

#### Cor Pulmonale

Cor pulmonale is right-sided heart failure secondary to pulmonary hypertension. Long-term oxygen therapy and diuretics have been the mainstays of therapy for cor pulmonale. Increasing the 

#### Polycythemia

Polycythemia secondary to chronic hypoxemia in COPD patients can be improved by either oxygen therapy or periodic phlebotomy if oxygen therapy alone is not sufficient. COT was shown by the Nocturnal Oxygen Therapy Trial Group to reduce hematocrit values in treated patients. Acute phlebotomy is indicated if the hematocrit is above 55% to 60% and the patient is experiencing central nervous system effects suggestive of sludging from high blood viscosity. Long-term oxygen can then be used to maintain a lower hematocrit.

| TABLE 34–14 Recommended Antimicrobial Therapy in Acute Exacerbations of COPD |
|------------------|------------------|------------------|
| **Likely Pathogens** | **Recommended Antimicrobial Therapy** |
| S. pneumoniae | Macrolide (azithromycin, clarithromycin) |
| H. influenzae | Second- or third-generation cephalosporin |
| M. catarrhalis | Doxycycline |
| H. parainfluenzae | Therapies not recommended: TMP/SMX, amoxicillin, first-generation cephalosporins, and erythromycin |
| Resistance uncommon | Amoxicillin/clavulanate Fluoroquinolone with enhanced pneumococcal activity (levofloxacin, gemifloxacin, moxifloxacin) |
| As above plus drug-resistant pneumococci, β-lactamase–producing H. influenzae and M. catarrhalis | Fluoroquinolone with enhanced pneumococcal activity (levofloxacin) |
| As above plus gram-negatives | IV therapy if required: β-lactamase resistant penicillin with antipseudomonal activity 3rd- or 4th-generation cephalosporin with antipseudomonal activity |

*TMP/SMX should not be used due to increasing pneumococcal resistance; amoxicillin and first-generation cephalosporins are not recommended due to β-lactamase susceptibility; and erythromycin is not recommended due to insufficient activity against H. influenzae.*

*In sepsis, double antipseudomonal coverage should be considered (e.g., addition of an aminoglycoside). Modified and updated from reference 7.*
OTHER PHARMACOLOGIC CONSIDERATIONS

A number of other treatments have been explored over the years. Among these therapies, either there is insufficient evidence to warrant recommending their use or they have been proven to not be beneficial in the management of COPD. A brief summary is provided because the clinician likely will encounter patients who are receiving or inquire about these treatments.

Suppressive Antimicrobial Agents

Because COPD patients often are colonized with bacteria and experience recurrent exacerbations of their condition, a common practice employed in the past has been the use of low-dose antimicrobial therapy as preventative or prophylaxis against these acute exacerbations. However, clinical studies over the past 40 years have failed to demonstrate any benefit from this practice. The role of antimicrobial therapy is limited to acute exacerbations of COPD meeting specific criteria.

Expectorants and Mucolytics

Adequate water intake generally is acceptable to maintain hydration and assist in the removal of airway sections. Beyond this, the regular use of mucolytics or expectorants for COPD patients has no proven benefit. This includes the use of saturated solutions of potassium iodide, ammonium chloride, acetylcysteine, and guaifenesin. In 2007, the FDA announced its intention to take action against several companies marketing unapproved timed-released formulations of guaifenesin. Two formulations are approved by the FDA (Humibid and Mucinex); however, data are lacking on their benefit.

Narcotics

Systemic (oral and parenteral) opioids, especially morphine, can relieve dyspnea for patients with end-stage COPD. Nebulized therapy is sometimes used in clinical practice although data about clinical benefit are lacking. Opioids should be used carefully, if at all, to avoid adverse effects on ventilatory drive.

Respiratory Stimulants

There is no role for respiratory stimulants in the long-term management of COPD. Agents that have shown some utility in the acute setting include almitrine and doxapram. However, almitrine is available only in Europe, and its usefulness is limited by neurotoxicity. Doxapram is available for intravenous use only and may be no better than intermittent NPPV.

Secondary pulmonary hypertension is a feature of severe COPD. This has prompted interest about the potential role of agents used to treat primary pulmonary hypertension. However, the use of an endothelin receptor antagonist (bosentan) failed to improve exercise tolerance and worsened hypoxemia in one trial.

DIETARY SUPPLEMENTS

There has been increasing interest in the role of antioxidants, including vitamins E and C and β-carotene, in reducing the frequency of exacerbations. It is postulated that they may be beneficial in COPD as a result of an imbalance between oxidants and antioxidants that has been considered in the pathogenesis of smoking-induced lung disease. However, there is no good evidence that antioxidant therapies improve COPD symptoms or slow disease progression. Nutritional supplements, including creatine, have not proven beneficial to improve the benefit of pulmonary rehabilitation programs.

SURGICAL INTERVENTION

Various surgical options have been employed in the management of COPD. These include bullectomy, lung volume reduction surgery (LVRS), and lung transplantation. Bullectomy has been performed for many years and may be useful when large bullae (>1 cm) are noted on computerized axial tomography (CT or CAT) scan. The presence of bullae may contribute to complaints of dyspnea, and their removal can improve lung function and reduce symptoms, although there is no evidence of a mortality benefit. Because of the prevalence of COPD, it is the most frequent indication for lung transplantation. Intervention is considered when predicted survival is less than 2 years, FEV1 is <25% predicted, and hypoxemia, hypercapnia, and pulmonary hypertension exists despite medical management. Experience to date shows 2-year survival of 655 to 90%, and 5-year survival of 415 to 53%.

Recent trials have evaluated the effect of bilateral lung volume reduction surgery (LVRS) for management of severe COPD. Short-term trials comparing the effects of pulmonary rehabilitation plus LVRS with pulmonary rehabilitation alone reported that the combination of treatments resulted in greater improvements in lung function, gas exchange, and quality of life at 3 months. Only recently have data evaluating the long-term effect of LVRS compared with pulmonary rehabilitation been published. The National Emphysema Treatment Trial (NETT), a prospective, randomized trial evaluating the long-term effects of LVRS plus pulmonary rehabilitation compared with pulmonary rehabilitation alone, followed 1,218 patients for 3 years. The primary end points for the study were mortality and maximal exercise capacity 2 years after randomization. Secondary end points included pulmonary function, distance walked in 6 minutes, and quality-of-life measurements. At an interim analysis, patients with an FEV1 of less than 20% of predicted or a carbon monoxide diffusing capacity of less than 20% of predicted were noted to be at high risk of death after surgery and subsequently were excluded from the study. Results of the study showed no mortality benefit with LVRS compared with pulmonary rehabilitation alone. Patients undergoing surgery had improved exercise capacity, lung function, and quality of life at 2 years, but these patients also had a higher risk of short-term morbidity and mortality associated with the surgery. A subgroup analysis of the study noted that patients with predominately upper-lobe emphysema and low exercise capacity undergoing surgery had lower mortality rates at 2 years compared with patients treated with medical therapy alone. Because of the costs and risks associated with LVRS, more studies are needed to better determine the ideal surgical candidates and identify subgroups of patients that would benefit most from surgery. The long-term benefits of LVRS are exhibited as improved P02 and decreased requirements for supplemental oxygen during treadmill walking as well as self-reported oxygen requirements for up to 24 months after the procedure.

INVESTIGATIONAL THERAPIES

Based on the knowledge about the importance of neutrophil inflammation in COPD and potential therapeutic benefit of inhibition of neutrophil activity, a number of antiinflammatory compounds are being explored. Specifically, agents inhibiting leukotriene B4, neutrophil elastase, and phosphodiesterases currently are being evaluated. To date, studies evaluating leukotriene-modifying therapies have been disappointing. Further studies are needed to evaluate the clinical benefit of such inhibitors for patients with COPD.

Phosphodiesterase 4 (PDE4) is the major phosphodiesterase found in airway smooth muscle cells and inflammatory cells and...
is responsible for degrading cAMP. Inhibition of PDE4 results in relaxation of airway smooth muscle cells and decreased activity of inflammatory cells and mediators such as TNF-α and IL-8. Two PDE4 inhibitors, cilomilast and roflumilast, have reached clinical trials. Cilomilast has been evaluated in several human trials and has been shown to improve expiratory airflow as measured by FEV₁ for patients with COPD when given at a dose of 15 mg twice daily for 6 weeks. To date, the results of clinical trials investigating these agents have been modest. Future studies of these agents should evaluate effects on other clinical outcomes such as health status, exacerbation frequency, and progression of disease.

Neutrophil elastase is implicated in the induction of bronchial disease, causing structural changes in lungs, impairment of mucociliary clearance, and impairment of host defenses. Protease inhibitors, namely, inhibitors of neutrophil elastase, are being investigated currently for the treatment of COPD.

Results have been disappointing in evaluating the benefit of infliximab, a tumor necrosis factor α-blocker, in treating COPD. A total of 234 patients with moderate to severe COPD received either infliximab 3 mg/kg or 5 mg/kg or placebo at baseline, 2, 6, 12, 18, and 24 weeks. Subjects completed a quality-of-life questionnaire [Chronic Respiratory Questionnaire (CRQ)] during treatment and out to 44 weeks. There were no differences on the CRQ or on any secondary end points including lung function, exercise capacity, or exacerbation rates. The discontinuation rate due to adverse events was high (20–27%) in the active treatment group.¹⁵⁴

**PHARMACOECONOMIC CONSIDERATIONS**

The overall cost of therapy is an important consideration in contemporary medical practice. Meaningful cost analysis goes beyond the cost of the medication itself and incorporates the impact of a given therapeutic agent on overall healthcare cost. Because of the relative lack of benefit among objective outcome measures in COPD clinical trials, pharmacoeconomic studies can be useful in decision making about pharmacotherapy options. Pharmacoeconomic analyses in COPD, although limited, are available regarding antibiotic use in acute exacerbations and some therapies for management of chronic stable COPD.

The costs of managing an acute exacerbation of COPD in the ambulatory setting was evaluated in over 2,400 patients. Subjects were followed for 1 month following the diagnosis of the exacerbation. The overall relapse rate was 21%, with 31% and 16% of subjects requiring care in the emergency department and hospital, respectively. The overall costs for exacerbation treatment averaged $159, with 58% attributed to hospitalization.¹⁵⁵ These authors concluded that a significant cost savings would result from improving the successful ambulatory management of acute exacerbations.

Grossman and colleagues conducted a trial investigating the use of aggressive antimicrobial therapy (ciprofloxacin) compared with usual antibiotic therapy (defined as any nonquinolone) in the treatment of acute exacerbations of COPD.¹⁵⁶ Overall, the results indicated no preference for either treatment arm. However, for patients who were categorized as high risk (severe underlying lung disease, more than four exacerbations per year, duration of bronchitis greater than 10 years, elderly, significant comorbid illness), the use of aggressive antibiotic therapy was associated with improved clinical outcome, higher quality of life, and fewer costs. The results of this study are consistent with Table 34–14, which suggests that higher-risk patients are likely to have more resistant strains of organisms and thus require more aggressive antimicrobial treatment.

Few data are available about the cost-effectiveness of educational programs for patients with COPD. In an outpatient clinic, patients attending one 4-hour group session, followed by one to two individual sessions with a clinician, reported improved outcomes, and costs were reduced in an evaluation 12 months later.¹⁵⁷ Additional research is needed regarding the best model for education and also the specific self-management strategies to teach.

Friedman and colleagues conducted a post hoc pharmacoeconomic evaluation of two multicenter, randomized trials comparing the combination of ipratropium and albuterol with both drugs used as monotherapy.¹⁵⁸ Patients who received a combination of ipratropium and albuterol had lower rates of exacerbations, lower overall treatment costs, and improved cost-effectiveness compared with either drug used alone. With the introduction of new bronchodilator therapies and with no clearly consistent advantage of one class of agents over another, pharmacoeconomic analyses may be useful for clinicians in determining the most appropriate therapy for their patients.

**CLINICAL CONTROVERSIES**

In the United States, all products containing a LABA agent, either alone or in combination with ICs, include a black box warning about an increased risk of severe asthma attacks or death associated with their use. This caution applies to patients with asthma, and it is strongly recommended that LABAs should be used always in conjunction with another controller therapy (e.g., ICs) and that use should be limited in duration. This concern only applies to patients with asthma and is not relevant concerning the use of LABA therapy for COPD patients.

A combination product of a long-acting inhaled β-agonist (salmeterol) and an inhaled corticosteroid agent (fluticasone) is one of the most commonly prescribed medications for lung disease, including COPD. However, in expert guidelines, ICs are indicated only for patients with more severe disease who experience frequent exacerbations. Many patients now receiving therapy with the combination inhaler may be candidates for bronchodilator therapy alone, although the benefit of ICs continues to be a focus of clinical research, including the potential for a mortality benefit.

The role of systemic corticosteroids for acute exacerbations of COPD has been clarified in recent years. However, the appropriate dosage regimen is not well established. Regimens range from initial high doses (methylprednisolone 125 mg every 6 hours) to more conservative dosing (prednisone 40–60 mg/day). Consensus guidelines indicate that bronchodilator therapy is the focus of pharmacotherapy for COPD. However, there is no clear choice for the initial agent. For patients with daily but not persistent symptoms, either ipratropium or albuterol offers advantages as initial therapy. Both also have limitations if chosen as the initial therapy.

International guidelines recommend long-acting bronchodilator therapy for patients with moderate to very severe disease or when symptoms are not adequately managed with short-acting agents or as needed therapy. When response to a single long-acting bronchodilator is not optimal, guidelines recommend the use of combinations. However, data are lacking presently about the therapeutic benefit of combinations of long-acting bronchodilators, and this approach is associated with substantial costs.
EVALUATION OF THERAPEUTIC OUTCOMES

To evaluate therapeutic outcomes of COPD effectively, the practitioner must first delineate between chronic stable COPD and acute exacerbations. In chronic stable COPD, pulmonary function tests should be assessed periodically and with any therapy addition, change in dose, or deletion of therapy. Because objective improvements often are minimal, subjective assessments are important. Other outcome parameters are commonly evaluated, including dyspnea score, quality-of-life assessments, and exacerbation rates, including visits to the emergency department or hospitalization. In acute exacerbations of COPD, white blood cell count, vital signs, chest x-ray, and changes in frequency of dyspnea, sputum volume, and sputum purulence should be assessed at the onset and throughout treatment of an exacerbation. In more severe exacerbations, ABGs and oxygen saturation also should be monitored. As with any drug therapy, patient adherence to therapeutic regimens, side effects, potential drug interactions, and subjective measures of quality of life also must be evaluated.

END-OF-LIFE CARE

Based on the natural course of COPD, characterized by the progressive decline in lung function and development of complications, consideration should be given to end-of-life decisions and advanced directives. Factors associated with expected mortality within 1 year have been identified. These include older age, diagnosis of depression, declining overall health status, hypercapnia, an FEV₁ of less than 30% predicted, ability to walk only a few steps without resting, more than one emergent hospitalization in the past year, and the presence of comorbidities, including congestive heart failure. An effective strategy to discuss end-of-life care involves the patient’s participation in identifying advanced directives. Patients should be assured that symptoms, including pain, will be managed and their dignity will be preserved. Specific issues that should be addressed include location and provider for terminal care, desires to use or withhold mechanical ventilation, and involvement of other family members in decisions on behalf of the patient.

ABBREVIATIONS

AAT: α₁-antitrypsin
BMI: body mass index
COPD: chronic obstructive pulmonary disease
D₂CO: diffusion capacity for carbon monoxide
DPI: dry powder inhaler

Pulmonary arterial hypertension (PAH) may be defined as a mean pulmonary artery pressure (mPAP) ≥25 mm Hg at rest with a pulmonary wedge pressure (also known as pulmonary artery occlusion pressure) or left ventricular end diastolic pressure (LVEDP) ≤15 mm Hg measured by right cardiac catheterization.

Regardless of the etiology, be it unknown or related to an associated medical condition, subgroups of PAH are based on similar clinical and pathological physiology.

Diagnosis of PAH is growing due to increased awareness and knowledge of the disease state, leading to earlier and improved evaluation and identification.

The underlying cause of PAH is a complicated amalgam of endothelial cell dysfunction, a procoagulant state, platelet activation, vasoconstriction, loss of relaxing factors, cellular proliferation, hypertrophy, fibrosis, and inflammation.

Patients with PAH present with exertional dyspnea, fatigue, weakness, and exertion intolerance. As the disease progresses, symptoms of right heart dysfunction and failure, such as dyspnea at rest, lower extremity edema, chest pain, and syncope, are seen.

The only way to make a definitive diagnosis of PAH is by right heart catheterization. The right heart catheterization provides important prognostic information and can be used to assess pulmonary vasoreactivity prior to initiating therapy.

The goals of treatment are to alleviate symptoms, improve the quality of life, slow the progression of the disease, and improve survival.

A general goal of PAH treatment is to correct the imbalance between vasoconstriction and vasodilation and prevent adverse thrombotic events to improve oxygenation and quality of life.

Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH.

Conventional therapy of PAH includes oral anticoagulants, diuretics, oxygen, and digoxin.

Prostacyclin analogs such as epoprostenol, treprostinil, and iloprost induce potent vasodilation of pulmonary vascular beds.

Endothelin receptor antagonists, bosentan, ambrisentan, and sitaxsentan, improve exercise capacity, hemodynamics, and functional class in PAH.

Phosphodiesterase-5 inhibitors, including sildenafil and tadalafil, are potent and highly specific drugs that have been shown to reduce mPAP and improve functional class.

Only a very small number of patients with PAH demonstrate a favorable response to acute vasodilator testing. These are the only patients amenable to therapy with calcium channel blocker.

Combination therapy in PAH may address more than one mechanism causing this disease. Combination therapy in clinical trials has provided additional benefit but more studies are needed.
PAH and are currently receiving treatment. In a French registry study of more than 600 patients with PAH, Humbert et al. found that the most common cause of PAH was IPAH (approximately 40%), followed by PAH associated with connective tissue diseases (15.3%), congenital heart disease (11.3%), portal hypertension (10.4%), and familial PAH (FPAH) (3.9%). Based on autopsy findings, PAH was found to occur in 0.13% of patients.

**ETIOLOGY**

PAH most often originates with a predisposing state and one or more inciting stimuli that has been referred to as the “multiple hit hypothesis.” Two or more hits may consist of a genetic disorder combined with one or more other genetic or environmental exposures or comorbidities. Once a permissive and provocative environment exists, multiple mechanisms can be activated leading to vascular constriction, cellular proliferation, and a prothrombotic state resulting in PAH and its sequelae. PAH can be associated with numerous conditions (Table 35–1) as well as being an idiopathic condition (IPAH). The World Health Organization classification of PAH defines five groups: pulmonary arterial hypertension, pulmonary hypertension owing to left heart disease, pulmonary hypertension owing to lung diseases and/or hypoxia, chronic thromboembolic pulmonary hypertension (CTEPH), and pulmonary hypertension with unclear multifactorial mechanisms. The incidence of IPAH is estimated to be five to six per 1 million in North America and Europe, with a marked female predominance (male-to-female ratio: 1:1.7) and a mean age at the time of recognition being approximately 37 years but with much variation. PAH is a common complication of scleroderma, with 7% to 12% of patients developing PAH. Patients with scleroderma who develop PAH seem to have markedly worse outcomes in comparison with other PAH subgroups. PAH may also be a complication from other connective tissue disorders, including systemic lupus erythematosus, mixed connective tissue disease, and lung fibrosis. Patients with human immunodeficiency virus (HIV) infection can develop PAH with a prevalence of 0.46%. In patients with liver disease, portal hypertension may cause concurrent pulmonary hypertension in an estimated 2% to 6% of patients. Congenital heart diseases may also precipitate development of PAH. Although uncommon in the United States, the most common forms of PAH worldwide are probably schistosomiasis and sickle cell disease followed by congenital heart disease and pulmonary hypertension of early childhood. PAH can be a complication of sickle cell disease and is a major independent risk factor for death. Drugs and toxins that definitively precipitate PAH include anorexic drugs such as aminorex, fenfluramine, and dexfenfluramine. Other drugs considered to be likely or possible causative agents for PAH include amphetamines, L-tryptophan, cocaine, and certain chemotherapeutic agents (mitomycin C, Carmustine, etoposide, cyclophosphamide, bleomycin). Rapseseed oil is also associated with PAH.

Hereditable PAH includes both IPAH with germline mutations and familial cases without an identified mutation. Germline mutations seen in PAH include bone morphogenetic protein receptor II (BMPR2) and activin receptor-like kinase type 1 (ALK-1). Mutations in the BMPR2 gene have been identified in approximately 70% of patients with familial PAH and in 11% to 40% of patients with IPAH. Genetic testing for BMPR2 and ALK-1 may be offered and professional genetic counseling should be provided.

**PATHOPHYSIOLOGY**

The pathobiology of PAH involves several key biologic events, including endothelial cell dysfunction, a procoagulant state, platelet activation, constricting factors, loss of relaxing factors, cellular proliferation, hypertrophy, fibrosis, and inflammation—all combining to produce progressive and deleterious pulmonary vascular remodeling (Fig. 35–1). Genetic substrates that are associated with PAH include BMPR2, ALK-1, nitric oxide synthase (ec-NOS), carboxyamidophosphate synthase gene, and 5-hydroxytryptamine (serotonin) transporter (5-HTT). A mutation of BMPR2 receptor is an aberration of signal transduction in the pulmonary vascular smooth muscle cell that is postulated to alter apoptosis favoring cellular proliferation. ALK-1 is part of the transforming growth factor-β superfamily and is seen in hereditary hemorrhagic telangiectasia and PAH. 5-HTT is associated with pulmonary artery smooth muscle cell proliferation and is present in IPAH in the homozygous form in 65% of patients. Dysregulation of serotonin (5-HT) synthesis mediated via tryptophan hydroxylases (Tph1 and Tph2) is closely linked to the hypoxic PAH phenotype in mice, and both Tph1 and Tph2 may contribute to PAH development. Known or suspected exposure to HIV infection should be explored. Molecular and cellular mechanisms are mediated by a variety of biologically active compounds, including prostacyclin (PGI2), endothelin-1, nitric oxide, and serotonin. PGI2 is a vasodilatory and
Antiproliferative substance that is produced by the endothelial cells, and the synthesis of PGI, and its circulating levels are reduced in PAH. Furthermore, thromboxane, a vasoconstrictor, is increased in PAH. Endothelin-1 is produced in the endothelium, and it possesses potent vasoconstrictor and mitogenic effects. Endothelin-1 levels are increased in PAH and clearance is reduced. Endothelin-1 acts via the endothelin receptors (ETA and ETB) to promote vascular smooth muscle proliferation and vasoconstriction. Plasma levels of endothelin-1 correlate with severity of PAH and prognosis. 

Nitric oxide (NO) is produced in the endothelium via NO synthase and leads to vasodilation and opening of cell membrane potassium channels to allow potassium ion efflux, membrane depolarization, and calcium channel inhibition. Voltage-dependent potassium channels (Kv 1.5) are inhibited by a number of stimuli that promote PAH, including hypoxia and fenfluramine, resulting in downregulated Kv 1.5 channels in patients with PAH. Entering calcium is a signal for release of sarcoplasmic calcium and activation of the contractile apparatus. NO promotes vasodilation through calcium channel inhibition. In PAH there is evidence of decreased NO synthase expression, leading to vasooconstriction and cell proliferation. Alteration in NO is a therapeutic target, and treatment approaches include inhibition of phosphodiesterase-5 or calcium channel blockade. Elevated 5-HT are thought to be involved. In IPAH endothelial dysfunction may occur as a result of proliferation of a monoclonal cell type leading to a plexiform lesion classically associated with this type of PAH. In addition, sleep-disordered breathing and obstructive sleep apnea are associated with cardiovascular morbidity. The reported range of prevalence of PAH in sleep-disordered breathing is 17% to 53%.

The signs and symptoms of PAH are highly variable depending on the stage of the disease and comorbidities (Table 35-2). In patients with a clinical suspicion of PAH, Doppler echocardiography should be performed as a noninvasive screening test that can detect increased pulmonary pressures, although it may be imprecise in determining actual pressures compared with cardiac catheterization.

catheterization.19 Echocardiography can also be used to assess treatment interventions and to follow disease progression.17 Because PAH commonly occurs in the setting of connective tissue disease, serologic markers for these diseases (e.g., scleroderma, systemic lupus erythematosus, rheumatoid arthritis, myositis) should be obtained to confirm or exclude these diagnoses.17 HIV is associated with an increased prevalence of PAH, and HIV testing should be done in the PAH workup.17,24,25 Chronic thromboembolic pulmonary hypertension should be evaluated with ventilation–perfusion lung scans and/or pulmonary angiography. Pulmonary function testing and arterial blood oxygenation should be evaluated, and the diffusing capacity of carbon monoxide may be particularly helpful in systemic sclerosis and PAH.17 Right-heart catheterization is the diagnostic “gold standard.” It establishes the diagnosis of PAH, evaluates pulmonary vasoreactivity, and guides therapy.17 In patients with PAH, serial determinations of functional class, exercise capacity (assessed by the 6-minute walk distance), and serial biomarkers provide benchmarks for disease severity, response to therapy, and progression.19

Right-heart catheterization provides important prognostic information and can be used to assess pulmonary vasoreactivity with the administration of fast-acting, short-duration vasodilators to determine the extent of vascular smooth muscle constriction and vasodilator response to calcium channel blockers (strength of recommendation: A for IPAH; E/C for associated pulmonary arterial hypertension [PAH]).17 Table 35–3 lists the grading criteria for recommendations. Table 35–4 lists commonly used agents and their dosages. The consensus definition of a positive response is defined as reduction of mPAP by at least 10 mm Hg to a value of 40 mm Hg or less. Patients with this response are most likely to have a beneficial hemodynamic and clinical response to treatment with calcium channel blockers.17 Those failing to achieve this response should not be treated with calcium channel blocker therapy. Those achieving this acute response may be treated with calcium channel blockers but need to be followed closely for safety and efficacy. Patients most likely to respond to calcium channel blockers are those with IPAH.17 Based on a study conducted by Sitbon et al. only approximately 13% will display acute vasoreactivity.24 About half of these patients lose this response when tested 1 year later. A significant vasodilator response may reflect an earlier stage of disease or a qualitatively different disease process.12

### Clinical Presentation of Pulmonary Arterial Hypertension

#### Symptoms
- Exertional dyspnea, fatigue, weakness, complaints of general exertion intolerance, dyspnea at rest as the disease progresses, exertional chest pain, syncope, lower extremity edema

#### Signs
- Accentuated component of S2 audible at the apex of the heart, early systolic ejection click, midsystolic ejection murmur, palpable left parasternal lift, right ventricular S3 gallop, and a prominent “a” wave.

#### Signs of Advanced Disease
- Diastolic murmur of pulmonary regurgitation and holosystolic murmur of tricuspid regurgitation, hepatomegaly, pulsatile liver, right ventricular S4 gallop, marked distension of jugular veins, peripheral edema, low blood pressure, diminished pulse pressure, cool extremities suggesting markedly reduced cardiac output and peripheral vasoconstriction; cyanosis (suggests right-to-left shunting), digital clubbing, rales, dullness, decreased breath sounds, accessory muscle use, wheezing, prolonged exhalation; peripheral venous insufficiency (suggests venous thrombosis or pulmonary thrombotic disease).

#### Diagnostic Tests
- Electrocardiogram for chamber enlargement, chest radiography to detect enlarged pulmonary arteries, Doppler echocardiography to calculate right ventricular/right atrial pressure and pulmonary diastolic pressure, pulmonary function testing and arterial blood oxygenation; ventilation-perfusion scanning, computed tomography, or magnetic resonance imaging can be used to exclude other diagnoses; right-heart catheterization may be used to confirm the presence of PAH and to guide therapy.

- Tests for connective disease or other risk factors.
TREATMENT

Pulmonary Arterial Hypertension

DESIRABLE OUTCOMES

The goals of treatment are alleviation of symptoms, improvement in the quality of life, prevention of disease progression, and improvement in survival. While the first two outcomes are clearly obtainable based on data from randomized trials, controversy exists over improvement in survival with current treatment regimens. In a meta-analysis performed by Macchia et al. of 16 trials involving 1,962 patients, no change in total mortality was seen. Up to 80% of the patients were in functional classes III/IV, with a median walking distance of 330 meters at baseline. Overall, experimental treatments were associated with a nonsignificant reduction in all-cause mortality, a minor but statistically significant improvement in exercise capacity, and an improved dyspnea status by at least one functional class. Changes in exercise capacity were not found to be predictive of a survival benefit. Because most of the patients had advanced disease, the potential for a reduction in mortality may have been minimized, and less severely ill patients may have better outcomes.

However, a recent meta-analysis by Galie et al. of 21 trials including 3,140 patients found different results. In contrast to the previous meta-analysis, this study included six new randomized, controlled trials not previously evaluated and excluded one trial performed in lung fibrosis patients. Investigators found that active treatment of PAH resulted in a 43% reduction in mortality. Patients experienced an improvement in exercise capacity, determined by change in 6-minute walk distance. Approximately half of the patients were functional class III at baseline. With active treatment, functional class improved and number of hospitalizations was reduced. This meta-analysis offers support that treatment does improve survival; unfortunately, overall mortality remains high. In addition, individual trials also show survival benefit, at least in the short term (i.e., 3 years).

GENERAL APPROACH TO TREATMENT

Treatment of PAH may be categorized into nonpharmacologic, surgical, and pharmacologic interventions.

The principal endothelial abnormalities that are current pharmacologic therapeutic targets include (a) supplementing endogenous vasodilators, (b) inhibiting endogenous vasoconstrictors, and (c) reducing endothelial platelet interaction and limiting thrombosis. Nonpharmacologic therapy can be quite broad and should be used when clinically appropriate. Surgical therapy is indicated in certain situations and includes atrial septostomy, pulmonary thromboendarterectomy for chronic thromboembolic pulmonary hypertension, and lung or heart–lung transplantation (for disease that is not responsive to medical therapy).

NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy is frequently used to address comorbid conditions that often accompany PAH. In patients with obstructive sleep apnea and PAH, positive airway pressure therapy should be provided. Pulmonary thromboendarterectomy for PAH caused by chronic, recurrent thromboembolic disease improves hemodynamics, functional status, and survival. Pregnancy should be avoided; all females of child-bearing age should be counseled on the risks of pregnancy due to high mortality rates. Immunization against influenza and pneumococcal disease should be provided according to standards for patients with serious cardiopulmonary disease. Hypoxemia may aggravate vasoconstriction in patients with PAH, and it is advisable to avoid hypobaric hypoxia starting with altitudes between 1,500 and 2,000 meters. Commercial airplanes are pressurized to equivalent altitude between 1,600 and 2,500 meters and supplemental oxygen in PAH patients should be considered. Patients should adhere to a diet of 2,400 milligrams of sodium or less per day to avoid fluid retention (predisposing to right-heart failure). Cardiopulmonary rehabilitation improves functional status and is safe and important for patients with PAH. Patients with PAH are sensitive to anemia. Complete blood count should be monitored and anemia treated as appropriate. Patients with long-standing hypoxia, such as those with right-to-left shunts, develop erythrocytosis. Phlebotomies may be indicated in symptomatic patients to prevent complications of hyperviscosity. PAH patients are affected by a variable degree of anxiety and/or depression that can have a profound impact on their quality of life. Support groups and psychological counseling can be helpful to improve understanding and acceptance of the disease.

Patients with PAH are frequently anticoagulated with warfarin; therefore, patients should avoid drugs that interact with warfarin or those that potentially increase the risk of gastrointestinal hemorrhage (e.g., nonsteroidal anti-inflammatory drugs such as ibuprofen and aspirin), as anticoagulation in PAH is frequently considered. Nonsteroidal antiinflammatory drugs may also worsen renal function and are of particular concern in patients with low cardiac output or azotemia. Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and β-blockers may cause hypotension and right-heart failure and should be used with caution in PAH.

PHARMACOLOGIC THERAPY

The number of potential therapies for PAH has expanded dramatically in the past decade. Multiple drugs have been developed specifically for treatment of PAH in addition to adjunctive therapy with anticoagulation and oxygen, as well as other therapies to treat comorbidities. Figure 35–2 illustrates the current recommended treatment algorithm based on the most recent guidelines.

Conventional Pharmacologic Treatment

Conventional therapy includes oral anticoagulants, diuretics, oxygen, and digoxin. The rationale for oral anticoagulants in patients with PAH is based on the presence of traditional risk factors for venous thromboembolism, such as heart failure and sedentary lifestyle, as well as on the demonstration of thrombotic predisposition and thrombotic changes in the pulmonary microcirculation. The target international normalized ratio in most centers is 1.5 to 2.5. In recent trials, 50% to 85% of patients have been anticoagulated; the highest prevalence has been in IPAH patients in New York Heart Association classes III and IV. Anticoagulation is recommended for patients with IPAH (strength of recommendation: E/B). Diuretics are used in patients with decompensated right-heart failure and with associated findings of increased central venous pressure, abdominal organ congestion, peripheral edema, and ascites. Appropriate diuretic therapy in right-heart failure allows clear symptomatic and clinical benefits in patients with PAH (strength of recommendation: E/A). Diuretics need to be used carefully as these patients should be maintained at as close to a euolemic state as possible. There are no randomized trials of diuretic therapy in PAH. Approximately 50% to 70% of patients with PAH receive diuretic therapy. Although oxygen saturation should be maintained at approximately 90%, there are no data currently available regarding the effects of long-term oxygen treatment in PAH (strength of recommendation: E/A). Oxygen treatment in patients with PAH associated with shunts (Eisenmenger syndrome) is controversial.

Digoxin use in PAH is based on judgment rather than scientific evidence of efficacy. Digoxin can be used for PAH patients with right-heart failure as adjunctive therapy along with diuretics to control symptoms. Digoxin may be useful in PAH patients who develop atrial flutter to slow ventricular rate. Current guidelines give digoxin a recommendation of E/C. There are no long-term trials,
Potent inhibitor of platelet aggregation and possesses cytoprotective and antiproliferative activities. Prostacyclin synthase expression is reduced in pulmonary arteries, and urinary excretion of prostacyclin metabolites is reduced in PAH. Epoprostenol (Flolan) is a synthetic analog of prostacyclin and has a short half-life of 3 to 5 minutes; consequently, it must be given by continuous intravenous infusion. In controlled trials lasting up to 3 months, epoprostenol improved 6-minute walk distance, hemodynamics, and clinical events. 34 – 36 Long-term epoprostenol is initiated at a dose ranging from 2 to 4 ng/kg/min and increased at a rate limited by side effects (flushing, headache, diarrhea, jaw pain, backache, abdominal cramping, foot/leg pain, and, rarely, hypotension). Because the drug must be given by a pump to provide a continuous infusion, infection, catheter obstruction, and sepsis are potential complications. A Centers for Disease Control and Prevention's benefit is uncertain. Optimal plasma concentrations for digoxin in PAH are unknown; however, in light of recent trials of digoxin in left systolic dysfunction, plasma concentrations should probably be in the range of 0.5 to 0.8 ng/mL. Patients on digoxin should receive periodic monitoring of potassium.

Specific Pharmacologic Therapy

In recent years, there has been a surge in availability of drug therapy for the treatment of PAH. Figure 35–3 illustrates the timeline of drug approval over the last few decades.

**Synthetic Prostacyclin and Prostacyclin Analogs**

Prostacyclin is produced predominantly by endothelial cells, and it induces potent vasodilation of all vascular beds. It is also a potent inhibitor of platelet aggregation and possesses cytoprotective and antiproliferative activities. Prostacyclin synthase expression is reduced in pulmonary arteries, and urinary excretion of prostacyclin metabolites is reduced in PAH. Epoprostenol (Flolan) is a synthetic analog of prostacyclin and has a short half-life of 3 to 5 minutes; consequently, it must be given by continuous intravenous infusion. In controlled trials lasting up to 3 months, epoprostenol improved 6-minute walk distance, hemodynamics, and clinical events. 34 – 36 Long-term epoprostenol is initiated at a dose ranging from 2 to 4 ng/kg/min and increased at a rate limited by side effects (flushing, headache, diarrhea, jaw pain, backache, abdominal cramping, foot/leg pain, and, rarely, hypotension). Because the drug must be given by a pump to provide a continuous infusion, infection, catheter obstruction, and sepsis are potential complications. A Centers for Disease Control and Prevention's benefit is uncertain. Optimal plasma concentrations for digoxin in PAH are unknown; however, in light of recent trials of digoxin in left systolic dysfunction, plasma concentrations should probably be in the range of 0.5 to 0.8 ng/mL. Patients on digoxin should receive periodic monitoring of potassium.

Specific Pharmacologic Therapy

In recent years, there has been a surge in availability of drug therapy for the treatment of PAH. Figure 35–3 illustrates the timeline of drug approval over the last few decades.

**Synthetic Prostacyclin and Prostacyclin Analogs**

Prostacyclin is produced predominantly by endothelial cells, and it induces potent vasodilation of all vascular beds. It is also a potent inhibitor of platelet aggregation and possesses cytoprotective and antiproliferative activities. Prostacyclin synthase expression is reduced in pulmonary arteries, and urinary excretion of prostacyclin metabolites is reduced in PAH. Epoprostenol (Flolan) is a synthetic analog of prostacyclin and has a short half-life of 3 to 5 minutes; consequently, it must be given by continuous intravenous infusion. In controlled trials lasting up to 3 months, epoprostenol improved 6-minute walk distance, hemodynamics, and clinical events. 34 – 36 Long-term epoprostenol is initiated at a dose ranging from 2 to 4 ng/kg/min and increased at a rate limited by side effects (flushing, headache, diarrhea, jaw pain, backache, abdominal cramping, foot/leg pain, and, rarely, hypotension). Because the drug must be given by a pump to provide a continuous infusion, infection, catheter obstruction, and sepsis are potential complications. A Centers for Disease
Treprostinil (Remodulin) is a stable analog of prostacyclin given for subcutaneous (SC) or intravenous (IV) infusion approved for functional classes II, III, and IV. The major advantages of treprostinil over epoprostenol include ease of use and increased safety due to a longer half-life, lowering the risk of rebound effects that may happen with drug interruption. Treprostinil has been shown to improve 6-minute walk distance and hemodynamics with outcomes that are similar to epoprostenol. In clinical trials, the greatest exercise improvement was observed in patients who were more compromised at baseline and in patients who could tolerate doses in the upper quartile (>13.8 ng/kg/min). The initial dose for treprostinil is 1.25 ng/kg/min by either the SC or the IV route. If not tolerated, the dose should be reduced to 0.625 ng/kg/min and retreatment attempted at 4 weeks. If transitioning from epoprostenol to treprostinil, start with 10% of the epoprostenol dose. Dose may be increased by 1.25 ng/kg/min but no more than 2.5 ng/kg/min per week. Infusion site pain is the most common side effect of treprostinil, leading to discontinuation of the treatment in 8% of patients and limiting dose increase in other patients. Other side effects are similar to epoprostenol. Based on international guidelines, treprostinil is recommended for functional class III (strength of recommendation: A) and functional class IV (strength of recommendation: B). Treprostinil experienced a 20-meter improvement in 6-minute walk distance compared with those on placebo (p <0.0006). All patients included in the trial were concurrently receiving bosentan or sildenafil for at least 3 months. An open-label extension of the trial found that inhaled treprostinil provided sustained benefit and was safe and efficacious over a 2-year period. The approved dosing of inhaled treprostinil is 3 breaths (18 mcg each) four times daily during waking hours. The dose may be titrated based on patient tolerance at 1- to 2-week intervals to maximum dose of 9 breaths four times daily. While inhaled treprostinil avoids the infusion-related complications of the other prostacyclin analogs, use is cautioned in patients with acute pulmonary infections or underlying lung disease. The most common adverse effects seen in clinical trials include throat irritation, cough, headache, nausea, dizziness, and flushing. Inhaled treprostinil may also cause systemic hypotension, and patients should be monitored carefully if they are concurrently on diuretics, antihypertensives, or other vasodilators. Further studies are being performed to evaluate the risk of oropharyngeal and pulmonary toxicities in patients on inhaled treprostinil. Current guidelines have not yet assigned a strength of recommendation for inhaled treprostinil use.

Iloprost (Ilomedin, Ventavis) is a prostacyclin analog that is given by inhalation using a dosing system provided by the manufacturer (ADD system) with the initial inhaled dose being 2.5 mcg 6 to 9 times/day up to every 2 hours during waking hours. The dose should be titrated and maintained at 5 mcg/dose if tolerated. In a 3-month, randomized, double-blind, placebo-controlled trial, iloprost via inhalation provided at least a 10% improvement in 6-minute walking distance and improvement in functional class. Iloprost may also be used as add-on therapy to bosentan. Adverse effects are similar to other prostacyclin analogs with the exception of infectious complications related to catheter use for drug delivery. Inhaled iloprost is indicated for functional class III (strength of recommendation: A) and functional class IV (strength of recommendation: B).

Endothelin Receptor Antagonists Endothelin-1 (ET-1), a peptide produced primarily by the vascular endothelial cells, is characterized as a powerful vasoconstrictor and mitogen for smooth muscle. Activation of the ET-1 system has been shown in both plasma and lung tissue of PAH patients. Bosentan (Tracleer) is an orally active dual ET A and ET B receptor antagonist that improves exercise capacity, functional class, hemodynamics, echocardiographic and Doppler variables, and time to clinical worsening. In one of the larger studies with bosentan, patients were started on 62.5 mg twice daily for 4 weeks followed by 125 mg or 250 mg twice daily for a minimum of 12 weeks. Both doses were better than placebo, and the higher dose provided greater improvement in 6-minute walking distance. Increases in hepatic aminotransferases occurred in 11% of patients and were dose dependent. The mechanism of increased liver enzymes is thought to be competition by bosentan and its metabolites with the biliary excretion of bile salts, resulting in retention of bile salts that can be cytotoxic to hepatocytes. Bosentan should be started at 62.5 mg twice daily in adults and adolescents for 4 weeks. After 4 weeks of therapy, the dose should be increased to 125 mg twice daily. If liver function tests are confirmed to be in the range of three to five times the upper limit of normal, reduce the daily dose or interrupt treatment. If liver function tests return to pretreatment levels, bosentan may be continued or reintroduced if indicated. Liver function tests should be monitored at baseline and monthly thereafter, and monthly pregnancy testing is required in females (category X). Complete blood count should be monitored every 3 months as bosentan has been associated with anemia. Bosentan is indicated for WHO functional class II and III (strength of

Phosphodiesterase Inhibitors

Sildenafil (Revatio) is a potent and highly specific phosphodiesterase-5 inhibitor that is approved for erectile dysfunction but also has been shown to reduce mPAP and improve functional class. Sildenafil exerts its pharmacologic effect by increasing the intracellular concentration of cyclic guanosine monophosphate, leading to vasorelaxation and antiproliferative effects on vascular smooth muscle cells. In a recent trial, sildenafil induced a significant reduction in mPAP and vascular resistance, and functional capacity improved (an average of +37 m). Sildenafil improved endothelial dependent vasodilation, and reduced plasma concentrations of endothelin-1 (from 4.5 ± 0.6 to 3.1 ± 0.7 pg/mL; \( p < 0.0001 \)) and von Willebrand factor (from 183.1 ± 10.1 to 149.1 ± 17.6 mU/mL; \( p < 0.0001 \)). In a year-long study, sildenafil in chronic thromboembolic pulmonary hypertension improved 6-minute walking distance and hemodynamics. Other studies have found similar beneficial results. The FDA-approved dose is 20 mg by mouth three times per day; however, much higher doses are routinely used clinically. Common adverse effects include headaches, flushing, epistaxis, dyspepsia, and diarrhea. Changes in vision have been reported, including blue-tinted vision and sudden loss of vision. In the event of sudden loss of vision, the drug should be stopped. Concurrent nitrate therapy may lead to excessive blood pressure reduction, and this combination should be avoided. Based on the current guidelines, sildenafil is recommended for functional class II and III patients with PAH (strength of recommendation: A) in addition to functional class IV patients (strength of recommendation: E/C). Another phosphodiesterase-5 inhibitor, tadalafil (Adcirca), was approved by the FDA in May 2009 for the treatment of PAH. In a 16-week study, tadalafil 40 mg daily significantly improved exercise capacity (an average of +33 m; \( p < 0.01 \)) and quality of life measures. Tadalafil 40 mg also improved the time to clinical worsening (\( p = 0.041 \)), which has not been demonstrated with sildenafil. Fifty-three percent of patients in this study were also on background bosentan therapy. Treatment-naïve patients demonstrated not only greater improvement in exercise capacity than those on bosentan therapy (\(+44 \text{ m vs. } 23 \text{ m}\)) but also greater improvement on all secondary outcomes. One possible explanation is decreased tadalafil levels as bosentan is a potent CYP450 3A4 inducer. Higher doses of tadalafil may be required in patients on concurrent bosentan therapy. The most commonly reported adverse events were headache, myalgia, and flushing. The recommended dose is 40 mg by mouth once a day. Concurrent use with nitrate therapy should also be avoided with tadalafil. Current guidelines indicate tadalafil for functional class II and III (strength of recommendation: B) and functional class IV (strength of recommendation: E/C).

Calcium Channel Blockers

A very small number of patients with IPAH demonstrating a favorable response to acute vasodilator testing will do well with calcium channel blockers (CCBs). As described previously, IPAH patients are most likely to respond to acute vasodilators and CCBs, but the number responding on long-term treatment is small (approximately 7%). Large reductions in MPAP predict a better response to long-term CCBs. The preferred drugs are dihydropyridine CCBs as they lack the negative inotropic effects seen with verapamil. Diltiazem may be used in patients with tachycardia to slow heart rate through atrioventricular node blockade. If left ventricular systolic dysfunction is present, diltiazem and verapamil should not be used. Assessment of CCB therapy should occur soon after initiation, and if improvement in functional class to class I or II is not seen, additional or alternative PAH therapy should be instituted. CCBs should not be used empirically to treat PAH in the absence of demonstrated acute vasoreactivity. In acute responders, calcium channel blockers may be used in WHO functional classes I through IV (strength of recommendation: B). The doses of these drugs are relatively high—that is, up to 120 to 240 mg/day for nifedipine and 240 to 720 mg/day for diltiazem—but initial doses should be much lower and titrated upward to response.

Combination Therapy

Combination therapy is an attractive option to address the multiple pathophysiologic mechanisms in PAH, resulting in improvement in hemodynamics, symptoms, and exercise capacity. Combination therapy can be pursued by the simultaneous initiation of two (or more) treatments or by the addition of a second (or third) agent if previous treatment has been insufficient. Potential indications for combination therapy include signs of right-heart failure, 6-minute walk distance <380 m, and persistent functional class III or IV symptoms despite active treatment. Hooper found that following a goal-oriented treatment approach using combinations of bosentan, sildenafil, and inhaled iloprost significantly improved the combined end point of death, lung transplantation, and need for intravenous iloprost treatment.

Bosentan, when combined with epoprostenol, improved hemodynamics, exercise capacity, and functional class, though this result was nonsignificant. In patients with PAH who are deteriorating despite chronic treatment with prostanoids, the addition of bosentan or sildenafil results in improvement in pulmonary hemodynamics and exercise based on uncontrolled studies. Addition of sildenafil to long-term epoprostenol therapy resulted in significant improvements in 6-minute walk distance, mPAP, cardiac output, and time to clinical worsening. Two studies have evaluated the combination of inhaled iloprost with existing bosentan therapy, and one found a nonsignificant improvement in 6-minute walk distance. One study was terminated early due to a futility analysis of the predetermined sample size. Addition of tadalafil to background bosentan therapy resulted in improvement in 6-minute walk distance. One study was terminated early due to a futility analysis of the predetermined sample size. Another study of tadalafil with placebo showed no improvement in primary end points.
Inhaled treprostinil in combination with bosentan or sildenafil also increased 6-minute walk distance. An increase in adverse effects may be experienced with combination therapy. Sequential combination therapy is recommended for patients with inadequate clinical response to monotherapy; combinations of prostanoids, phosphodiesterase-5 inhibitors, and endothelin antagonists may be used (strength of recommendation: B). Initial combination therapy may be necessary in WHO functional class IV patients (strength of recommendation: E/C). More specific information concerning individual drugs used for PAH are shown in Table 35–5, and a summary of evidence for combination therapy is shown in Table 35–6.

**Phosphodiesterase inhibitors**

**Sildenafil (Revatio)**

- Increases the intracellular concentration of cyclic guanosine monophosphate (cGMP) resulting in vasorelaxation and antiproliferative effects on smooth muscle cells
- Bioavailability 40% 96% protein bound Metabolized by CYP450 3A4 (major) and 2C9 (minor) Half-life 4 hours
- Headache, flushing, dyspepsia, nasal congestion, dizziness, and rash
- Known inhibitors of CYP3A4 and 2C9 (e.g., bosentan, cinetidine, fluvoxamine) Known inducers of CYP3A4 (e.g., rifampin, carbamazepine) Concurrent use with nitrates potentiates hypotensive effects
- 20 mg orally three times daily, taken at least 4–6 hours apart, 50 mg twice daily may be appropriate for more severe cases No greater efficacy with higher doses

**Tadalafil (Adcirca)**

- Increases the intracellular concentration of cyclic guanosine monophosphate (cGMP) resulting in vasorelaxation and antiproliferative effects on smooth muscle cells
- Bioavailability unavailable 94% protein bound Metabolized by CYP4503A4 (major) Half-life 15 hours
- Headache, flushing, dyspepsia, myalgia, nausea, nasal congestion, nasopharyngitis, pain in extremity
- Known inhibitors of CYP3A4 (e.g., bosentan, amiodarone) Known inducers of CYP3A4 (e.g., rifampin, carbamazepine) Concurrent use with nitrates potentiates hypotensive effects
- 40 mg orally once daily, with or without food Not recommended to divide the dose

**Calcium channel blockers**

**Nifedipine extended release** (Procardia XL, Nifedical XL, Adalat CC)

- Blocks the influx of extracellular calcium, causing vasodilation; more potent vasodilator than diltiazem
- Bioavailability 90% Extensive first-pass effect reduces bioavailability to 86% Metabolized by CYP3A4 Half-life 2–5 hours
- Peripheral edema, headache, dizziness, constipation, flushing
- Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin) Known 3A4 inducers (e.g., rifampin, carbamazepine) | Start at reduced dose of 30 mg orally twice daily and titrate to 120–240 mg daily

**Diltiazem** (Cardia XT, Cardizem CD, LA, SR, Tactia XT)

- Blocks the influx of extracellular calcium, causing vasodilation
- Bioavailability 80% Extensive first pass effect reduces bioavailability to 40% to 60% Metabolized by CYP3A4 Half-life 4–6 hours
- Gastrointestinal effects, negative inotropic effects, headache, flushing, peripheral edema
- Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin) Known inhibitors of CYP3A4 (e.g., rifampin, carbamazepine) Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin)
- Start at reduced dose of 60 mg orally three times daily and titrate to 240–720 mg daily

**Amlodipine** (Norvasc)

- Blocks the influx of extracellular calcium, causing vasodilation; more potent vasodilator than diltiazem
- Bioavailability 52% to 88% 93% protein bound Metabolized by CYP3A4 Half-life 35 hours
- Palpitations, peripheral edema, fatigue, dizziness, headache, flushing
- Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin) Known inhibitors of CYP3A4 (e.g., amiodarone, erythromycin)
- Start at reduced dose of 2.5 mg orally daily, titrated to maximum dose of 40 mg daily
Investigational Therapy

There are a few new agents within currently approved drug classes that are under investigation for use in PAH. Oral treprostinil is currently being evaluated in a series of studies known as the FREEDOM trials. FREEDOM-C (oral treprostinil in combination with an endothelin receptor antagonist and/or phosphodiesterase-5 inhibitor for the treatment of PAH) is a multicenter, randomized, double-blind trial evaluating oral treprostinil in patients already receiving an endothelin receptor antagonist and/or a phosphodiesterase-5 inhibitor. The trial found a nonsignificant improvement in 6-minute walk distance in patients on oral treprostinil for 16 weeks.54 Macitentan, an ET<sub>A</sub>/ET<sub>B</sub> receptor antagonist, is under evaluation in a phase III trial (SERAPHIN).55

There are also novel pathways in the pathogenesis of PAH that may provide potential new targets for therapy. These include vasoactive intestinal polypeptide, Rho kinase inhibitors, serotonin receptor antagonists and transporter blockers, HMG-CoA reductase inhibitors, and platelet-derived growth factor.17,20 Other strategies for PAH treatment include targeting angiogenesis, right ventricular remodeling, and endothelial progenitor cell therapy.66

**EVALUATION OF THERAPEUTIC OUTCOMES**

Response to treatment in PAH can be objectively measured by the 6-minute walk distance, echocardiography to assess pulmonary pressures, and right-heart catheterization as the gold standard to assess ventricular function and pulmonary pressures. The WHO functional classification system is clinically useful, but correlations to hemodynamics may be imprecise. Other outcomes that are useful in clinical trials include hospitalization for exacerbations of PAH and the development of complications and death.65

**CONCLUSIONS**

PAH is a challenging disease to manage; however, with the development of endothelin antagonists, phosphodiesterase inhibitors, and prostacyclin analogs, clinical improvement is possible in most patients, leading to a better quality of life and delay of disease progression. Patient education is important to improve acceptance of this disease and referral to specialty care centers that may provide the best outcomes.

CHAPTER 36
Drug-Induced Pulmonary Diseases
HENGAMEH H. RAISY, MICHELLE HARKINS, AND PATRICIA L. MARSHIK

KEY CONCEPTS

1. Select populations may be more susceptible to toxicities associated with specific agents.
2. Primary treatment is discontinuation of the offending agent and supportive care.

The manifestations of drug-induced pulmonary diseases span the entire spectrum of pathophysiologic conditions of the respiratory tract. As with most drug-induced diseases, the pathological changes are nonspecific. Therefore, the diagnosis is often difficult and, in most cases, is based on exclusion of all other possible causes. In addition, the true incidence of drug-induced pulmonary disease is difficult to assess as a result of the pathological nonspecificity and the interaction between the underlying disease state and the drugs.

Considering the physiologic and metabolic capacity of the lung, it is surprising that drug-induced pulmonary disease is not more common. The lung is the only organ of the body that receives the entire circulation. In addition, the lung contains a heterogeneous population of cells capable of various metabolic functions, including N-alkylation, N-dealkylation, N-oxidation, reduction of N-oxides, and C-hydroxylation.

Evaluation of epidemiologic studies on adverse drug reactions provides a perspective on the importance of drug-induced pulmonary disease. In a 2-year prospective survey of a community-based general practice, 41% of 817 patients experienced adverse drug reactions. Four patients, or 0.5% of the total respondents, experienced adverse respiratory symptoms. Respiratory symptoms occurred in 1.2% of patients experiencing adverse drug reactions. In a recent retrospective analysis of clinical case series in France, 898 patients had reported drug allergy, with a bronchospasm incidence of 6.9%. When these patients were rechallenged with the suspected drug, only 241 (17.6%) tested positive. The incidence of bronchospasm in patients with positive provocation test was 7.9%.

Adverse pulmonary reactions are uncommon in the general population but are among the most serious reactions, often requiring intervention. In a study of 270 adverse reactions leading to hospitalization from two populations, 3.0% were respiratory in nature. Of the reactions considered to be life threatening, 12.3% were respiratory. An early report on death caused by drug reactions from the Boston Collaborative Drug Surveillance Program indicated that 7 of 27 drug-induced deaths were respiratory in nature. This was confirmed in a follow-up study in which 6 of 24 drug-induced deaths were respiratory in nature.

DRUG-INDUCED APNEA

Apnea may be induced by central nervous system depression or respiratory neuromuscular blockade (Table 36–1). Patients with chronic obstructive airway disease, alveolar hypoventilation, and chronic carbon dioxide retention have an exaggerated respiratory depressant response to narcotic analgesics and sedatives. In addition, the injudicious administration of oxygen in patients with carbon dioxide retention can worsen ventilation-perfusion mismatching, producing apnea. Although the benzodiazepines are touted as causing less respiratory depression than barbiturates, they

F, frequent; I, infrequent; R, rare.
may produce a profound additive or synergistic effect when taken in combination with other respiratory depressants. Combining intravenous diazepam with phenobarbital to stop seizures in an emergency department frequently results in admissions to an intensive care unit for a short period of assisted mechanical ventilation, regardless of the drug administration rate. Too rapid intravenous administration of any of the benzodiazepines, even without coadministration of other respiratory depressants, will result in apnea. The risk appears to be the same for the various available agents (diazepam, lorazepam, and midazolam). Respiratory depression and arrests resulting in death and hypoxic encephalopathy have occurred following rapid intravenous administration of midazolam for conscious sedation prior to medical procedures. This has been reported more commonly in the elderly and the chronically debilitated or in combination with opioid analgesics. Concurrent use of inhibitors of cytochrome P450 3A4 with benzodiazepines is likely to lead to greater risk of respiratory depression.

1. Prolonged apnea may follow administration of any of the neuromuscular blocking agents used for surgery, particularly in patients with hepatic or renal dysfunction. In addition, persistent neuromuscular blockade and muscle weakness have been reported in critically ill patients who are receiving neuromuscular blockers continuously for more than 2 days to facilitate mechanical ventilation. This has resulted in delayed weaning from mechanical ventilation and prolonged intensive care unit stays. The prolonged neuromuscular blockade has been confined principally to pancuronium and vecuronium in patients with renal disease. Both agents have pharmacologic active metabolites that are excreted mainly in the urine. The emergence of renal failure has been associated with a 46% increase in risk of asthma symptoms at the age of 6 to 7 years. These findings should be interpreted with caution since confounding by indication may play a part in this association. The aminoglycosides—asthma/COPD association may be explained by reduction of glutathione, an endogenous antioxidant enzyme in the airway epithelium resulting in oxidant damage in the lung.

1. Administration of acetaminophen in the first year of life was associated with a 46% increase in risk of asthma symptoms at the age of 6 to 7 years. These findings should be interpreted with caution since confounding by indication may play a part in this association. The administration of acetylcysteine—asthma/COPD association may be explained by reduction of glutathione, an endogenous antioxidant enzyme in the airway epithelium resulting in oxidant damage in the lung.

**DRUG-INDUCED ASTHMA**

Bronchoconstriction is the most common drug-induced respiratory problem. Bronchospasm can be induced by a wide variety of drugs through a number of disparate pathophysiologic mechanisms (Table 36–2). Regardless of the pathophysiologic mechanism, drug-induced bronchospasm is almost exclusively a problem of patients with preexisting bronchial hyperreactivity (e.g., asthma, COPD).

By definition, all patients with nonspecific bronchial hyperreactivity will experience bronchospasm if given sufficiently high doses of cholinergic or anticholinesterase agents. Severe asthmatics with a high degree of bronchial reactivity may wheeze following the inhalation of a number of particulate substances, such as the lactose in dry-powder inhalers and inhaled corticosteroids, presumably through direct stimulation of the central airway irritant receptors. Other pharmacologic mechanisms for inducing bronchospasm include \( \beta_2 \)-receptor blockade and nonimmunologic histamine release from mast cells and basophils. A large number of agents are capable of producing bronchospasm through immunoglobulin (Ig)E-mediated reactions. These drugs can become a significant occupational hazard for pharmacists, nurses, and pharmaceutical industry workers.

**ASPIRIN-INDUCED BRONCHOSPASM**

Aspirin sensitivity or intolerance occurs in 4% to 20% of all asthmatics. The frequency of aspirin-induced bronchospasm increases with age. Patients older than age 40 years have a frequency approximately four times that of patients younger than 20 years. The frequency increases to 14% to 23% in patients with nasal polyps. Women predominate over men, and there is no evidence for a genetic or familial predisposition. The classic description of the aspirin-intolerant asthmatic includes the triad of severe asthma, nasal polyps, and aspirin intolerance. The typical patient experiences intense vasomotor rhinitis, which may or may not be associated with aspirin exposure, beginning during the third or fourth decade of life. Over a period of months, nasal polyps begin to appear, followed by severe asthma exacerbated by aspirin. Bronchospasm typically begins within minutes to hours following ingestion of aspirin and is associated with rhinorrhea, flushing of the head and neck, and conjunctivitis. The reactions are severe and often life threatening.

All aspirin-sensitive asthmatics do not fit the classic "aspirin triad" picture, and not all patients with asthma and nasal polyps develop sensitivity to aspirin. In most cases, aspirin-sensitive asthmatics are clinically indistinguishable from the general population of asthmatics except for their intolerance to aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs). Aspirin-induced asthmatics are not at higher risk of having fatal asthma if aspirin and other NSAIDs are avoided.

Diagnosis of aspirin-induced asthma requires a detailed medical history. The definitive diagnosis is made by aspirin provocation tests, which may be done via different routes. An oral provocation test is used commonly where threshold doses of aspirin induce a positive

**DRUG-INDUCED ASTHMA**

Epidemiologic studies demonstrate an increase in the prevalence of asthma and COPD with increased use of acetaminophen. The use of aspirin or ibuprofen is not associated with asthma or COPD. The association between use of acetaminophen in infancy and childhood and risk of childhood asthma was reported by the International Study of Asthma and Allergies in Childhood, including data from 31 countries. Administration of acetylcysteine—the first year of life was associated with a 46% increase in risk of asthma symptoms at the age of 6 to 7 years. These findings should be interpreted with caution since confounding by indication may play a part in this association. The aminoglycosides—asthma/COPD association may be explained by reduction of glutathione, an endogenous antioxidant enzyme in the airway epithelium resulting in oxidant damage in the lung.

Anticholinesterases
β-Adrenergic agonists
Ethylenediamine tetraacetic acid

A very small percentage (5%) of aspirin-sensitive patients react to acetaminophen and phenacetin.

When lysine-aspirin bronchoprovocation was compared with oral aspirin provocation, both methods were equally sensitive.

PATHOGENESIS

Aspirin-induced asthma is correctly classified as an idiosyncratic reaction in that the pathogenesis is still unknown. Patients with aspirin intolerance have increased plasma histamine concentrations after ingestion of aspirin and elevated peripheral eosinophil counts. All attempts to define an immunologic mechanism have been unsuccessful. Chemically similar drugs such as salicylamide and choline salicylate do not cross-react, whereas a large number of chemically dissimilar NSAIDs do produce reactions. Table 36–3 lists the analgesics that do and do not cross-react with aspirin. The currently accepted hypothesis of aspirin-induced asthma is that aspirin intolerance is integrally related to inhibition of cyclooxygenase. This is supported by the following evidence: (a) All NSAIDs that inhibit cyclooxygenase produce reactions, (b) the degree of cross-reactivity is proportional to the potency of cyclooxygenase inhibition, and (c) each patient with aspirin sensitivity has a threshold dose for precipitating bronchospasm that is specific for the degree of cyclooxygenase inhibition produced, and once established, the dose of another cyclooxygenase inhibitor needed to induce bronchospasm can be estimated.

The mechanism by which cyclooxygenase inhibition produces bronchospasm in susceptible individuals is unknown. Arachidonic acid metabolism through the 5-lipoxygenase pathway may lead to the excess production of leukotrienes C₄ and D₄. Leukotrienes C₄, D₄, and E₄ produce bronchospasm and promote histamine release from mast cells. The precise mechanism by which augmented leukotriene production occurs is unknown, and available hypotheses do not explain why only a small number of asthmatic patients react to aspirin and NSAIDs.

DESENSITIZATION

Patients with aspirin sensitivity can be desensitized. The ease of desensitization correlates with the sensitivity of the patient. Highly sensitive patients who react initially to less than 100 mg aspirin require multiple rechallenges to produce desensitization. Desensitization
usually persists for 2 to 5 days following discontinuance, with full sensitivity reestablished within 7 days.15 Cross-desensitization has been established between aspirin and all NSAIDs tested to date. Because patients may experience life-threatening reactions, desensitization should be attempted only in a controlled environment by personnel with expertise in handling these patients. In addition, there are reports of patients who have failed to maintain a desensitized state despite continued aspirin administration.15,16 In one open follow-up trial in 172 aspirin-sensitive asthmatics who had undergone desensitization and continued daily aspirin treatment (1,300 mg/day) an improvement in nasal-sinus and asthma symptoms occurred after 6 months of treatment, which persisted up to 5 years.22

**CROSS-SENSITIVITY WITH FOOD AND DRUG ADDITIVES**

1. Up to 80% of aspirin-sensitive asthmatics will have an adverse reaction to the yellow azo dye tartrazine (FD&C Yellow No. 5), which is used widely for coloring foods, drinks, drugs, and cosmetics.14 However, the studies reporting high cross-reactivity were poorly controlled and often used only subjective criteria.14,23,24 In double-blind, placebo-controlled trials using pulmonary function testing, sensitivity to tartrazine has proved to be a rare event.25 Tartrazine sensitivity appears to occur only in aspirin-intolerant patients at a prevalence of 2%.26 Although rare, owing to the severity of reaction and widespread use of tartrazine, the U.S. Food and Drug Administration (FDA) requires labeling for the products containing this dye.24 The likely mechanism is dose-related histamine release, and the clinical presentation is the same as the reaction to aspirin in aspirin-sensitive patients.24

Reactions to other azo dyes, monosodium glutamate, parabens, and nonazo dyes have been reported much less frequently than reactions to tartrazine and have been equally difficult to confirm with controlled challenges.27 Positive reactions to sodium benzoate, a food preservative, have been reported in as many as 23% of aspirin-sensitive individuals.14 Acetaminophen is a weak inhibitor of cyclooxygenase. As such, approximately 5% of aspirin-sensitive asthmatics will experience reactions to acetaminophen.25 Most aspirin-sensitive asthmatics can use acetaminophen as a safe alternative to aspirin. There is a growing body of evidence that selective cyclooxygenase-2 inhibitors may be used safely in aspirin-sensitive patients.14,24-28 but long-term studies with these agents should be undertaken to confirm their safe use in aspirin-sensitive patients. At this point, the package inserts of these agents state that they are contraindicated for aspirin-sensitive asthmatics.24,25,27 Sporadic cases of worsening bronchospasm and anaphylaxis have been reported in aspirin-sensitive asthmatics receiving intravenous hydrocortisone succinate, but such reactions have not been reported with use of other corticosteroids.18 It is not known whether it is the hydrocortisone or the succinate that is the problem.

**TREATMENT**

**Aspirin-Sensitive Asthma**

2. Therapy of aspirin-sensitive asthmatics takes one of two general approaches: desensitization or avoidance. Avoidance of triggering substances seldom alters the clinical course of patients’ asthma. The therapy of asthma has been nonspecific; however, in theory, 5-lipoxygenase inhibitors such as zileuton or leukotriene antagonists should provide specific therapy. A few studies have investigated use of leukotriene modifiers to prevent aspirin-induced bronchospasm in aspirin-sensitive asthmatic patients.28-31 Pretreatment with zileuton in eight aspirin-sensitive asthmatic patients protected them from the same threshold-provoking doses of aspirin.29 However, larger, escalating doses of aspirin above the threshold challenge doses were not examined in this study. Furthermore, when doses of aspirin were escalated above the threshold provocative doses, zileuton did not prevent formation of leukotrienes.28 In a similar study, pretreatment with montelukast 10 mg/day did not protect patients when aspirin doses were increased above their threshold doses.31 In another study, the mean provoking dose of aspirin did not differ in the asthmatics who were taking leukotriene modifiers and the control group (60.4 mg vs. 70.3 mg, respectively).28 Although initial studies suggested that leukotriene modifiers blocked aspirin-induced reactions, it is now apparent that they merely shift the dose-response curve to the right, leaving the patient at risk at higher doses. Thus even patients who might benefit from leukotriene modifiers should avoid aspirin and all NSAIDs. A case of ibuprofen 400-mg—induced asthma was reported in an asthmatic patient on zafirlukast 20 mg twice daily.32 Furthermore, most of the challenge studies are based on incremental doses of aspirin or NSAIDs, and exposure of patients to full clinical doses of aspirin or NSAIDs can overcome the antagonistic effect of leukotriene modifiers. The respiratory symptoms can be decreased but not prevented by pretreatment with antihistamines, cromolyn, and nedocromil.33-35 The long-term asthma control of patients with aspirin sensitivity does not differ from that for other asthmatics. There is no evidence to support that aspirin-sensitive asthmatics respond better to leukotriene modifiers. In a double-blind, randomized, placebo-controlled study, aspirin-sensitive asthmatic patients on montelukast showed a 10% improvement in FEV1 compared with the placebo group.33 Similar results were reported when montelukast was compared with placebo in patients with intermittent or persistent asthma.38

**β-BLOCKERS**

1. β-Adrenergic receptor blockers comprise the other large class of drugs that can be hazardous to a person with asthma. Even the more cardioselective agents such as acebutolol, atenolol, and metoprolol have been reported to cause asthma attacks.13 Patients with asthma may take nonselective and β1-selective blockers without incident for long periods; however, the occasional report of fatal asthma attacks resistant to therapy with β-agonists should provide ample warning of the dangers inherent in β-blocker therapy.13

If a patient with bronchial hyperreactivity requires β-blocker therapy, one of these selective β1-blockers (e.g., acebutolol, atenolol, metoprolol, or pindolol) should be used at the lowest possible dose. In a meta-analysis of 29 clinical trials in patients with mild to moderate airway obstruction, cardioselective β-blockers did not produce any clinically significant respiratory effects in short term.36 Celiprolol and betaxolol appear to possess greater cardioselectivity than currently marketed drugs.40-42 Fatal status asthmaticus has occurred with the topical administration of the nonselective timolol maleate ophthalmic solution for the treatment of open-angle glaucoma.43 Early investigations with ophthalmic betaxolol suggest that it is well tolerated even in timolol-sensitive asthmatics.43,44

**SULFITES**

Severe, life-threatening asthmatic reactions following consumption of restaurant meals and wine have occurred secondary to ingestion of the food preservative potassium metabisulﬁte.25 Sulfites have been used for centuries as preservatives in wine and food. As antioxidants, they prevent fermentation of wine and discoloration of fruits and vegetables caused by contaminating bacteria.45 Previously, sulfites had been given “generally recognized as safe”
status by the FDA. Sensitive patients react to concentrations ranging from 5 to 100 mg, amounts that are consumed routinely by anyone eating in restaurants. Consumption of sulfites in U.S. diets is estimated to be 2 to 3 mg/day in the home with 5 to 100 mg per 30 mL of beer or wine consumed. Anaphylactic or anaphylactoid reactions to sulfites in nonasthmatics are extremely rare. In the general asthmatic population, reactions to sulfites are uncommon. Approximately 5% of steroid-dependent asthmatics demonstrate sensitivity to sulfiting agents, but the prevalence is only around 1% in non—steroid-dependent asthmatic patients.

MECHANISM

Three different mechanisms have been proposed to explain the reaction to sulfites in asthmatic patients. The first is explained by the inhalation of sulfur dioxide, which produces bronchoconstriction in all asthmatics through direct stimulation of afferent parasympathetic irritant receptors. Furthermore, inhalation of atropine or the ingestion of doxepin protects sulfite-sensitive patients from reacting to the ingestion of sulfites. The second theory, IgE-mediated reaction, is supported by reported cases of sulfite-sensitive anaphylaxis reaction in patients with positive sulfite skin test. Finally, a reduced concentration of sulfite oxidase enzyme (the enzyme that catalyzes oxidation of sulfites to sulfates) compared with normal individuals has been demonstrated in a group of sulfite-sensitive asthmatics.

A number of pharmacologic agents contain sulfites as preservatives and antioxidants. The FDA now requires warning labels on drugs containing sulfites. Most manufacturers of drugs for the treatment of asthma have discontinued the use of sulfites. In addition, labeling is required on packaged foods that contain sulfites at 10 parts per million or more, and sulfiting agents are no longer allowed on fresh fruits and vegetables (excluding potatoes) intended for sale.

Pretreatment with cromolyn, anticholinergics, and cyanocobalamin have protected sulfite-sensitive patients. Presumably, pharmacologic doses of vitamin B12 catalyze the nonenzymatic oxidation of sulfite to sulfate.

OTHER PRESERVATIVES

Both ethylenediamine tetraacetic acid (EDTA) and benzalkonium chloride, used as stabilizing and bacteriostatic agents, respectively, can produce bronchoconstriction. In addition to producing bronchoconstriction, EDTA potentiates the bronchial responsiveness to histamine. These effects presumably are mediated through calcium chelation by EDTA. Benzalkonium chloride is more potent than EDTA, and its mechanism appears to be a result of mast cell degranulation and stimulation of irritant C fibers in the airways. The bronchoconstriction from benzalkonium chloride can be blocked by cromolyn but not the anticholinergic ipratropium bromide.

Benzalkonium chloride is found in the commercial multiple-dose nebulizer preparations of ipratropium bromide and beclomethasone dipropionate marketed in the United Kingdom and Europe and is presumed to be in part responsible for paradoxical wheezing following administration of these agents. Benzalkonium chloride is also found in albuterol nebulizer solutions marketed in the United States and has been implicated as a possible cause of paradoxical wheezing in infants receiving this preparation. The effect of these agents on FEV1 when used in the amount administered for treatment of acute asthma was evaluated in subjects with stable asthma. Patients were assigned randomly to inhale up to four 600-mcg nebulized doses of EDTA and benzalkonium chloride and normal saline. The change in FEV1 was not different between EDTA and the placebo group; however, benzalkonium chloride was associated with a statistically significant decrease in FEV1, compared with placebo. It is important to consider that these agents are always used in combination with bronchodilators and β2-agonists, which are potent mast cell stabilizers, and the anecdotal reports have not yet been confirmed with controlled investigations.

CONTRAST MEDIA

Iodinated radiocontrast materials are the most common cause of anaphylactoid reactions producing bronchospasm. Allergy to natural rubber latex, first reported in 1989 in the United States, is a common cause of occupational allergy for healthcare workers. Natural rubber is a processed plant product from the commercial rubber tree, Hevea brasiliensis. Latex allergens are proteins found in both raw latex and the extracts used in finished rubber products. Latex gloves are the largest single source of exposure to the protein allergens. The reported prevalence of latex allergy depends on the sample population. In the general population, latex allergy is less than 1%; however, the prevalence increases in healthcare workers to 5% to 15%. Risk factors for latex allergy include frequent exposure to rubber gloves, history of atopic disease, and presence of hand dermatitis. Patients with spina bifida are at an increased risk of latex allergy, with an incidence of 24% to 60% as a result of early and repeated exposure to rubber devices during the surgical procedures.

Clinical manifestations of latex allergy range from contact dermatitis and urticaria, rhinitis and asthma, and reported cases of anaphylaxis. The early manifestation of rubber allergy is contact urticaria, which is an IgE-mediated reaction to rubber proteins following direct contact with the medical devices: mainly rubber gloves. Contact dermatitis may occur within 1 to 2 days. Contact dermatitis is a cell-mediated delayed-type hypersensitivity reaction to the additive chemical component of rubber products. Rhinitis and asthma may follow inhalation of allergens carried by cornstarch powder used to coat the latex gloves. Asthma caused by occupational exposure is seen mostly in atopic patients with histories of seasonal and perennial allergies and asthma. Isolated cases of wheezing secondary to latex exposure in patients without a history of asthma have also been reported.

The diagnosis of latex allergy is based on the presence of latex-specific IgE, as well as symptoms consistent with IgE-mediated reactions. The mainstay of therapy for latex allergy is avoidance. The FDA requires appropriate labeling for all medical devices containing natural rubber latex to ensure avoidance and a latex-free environment. The role of pretreatment with antihistamines, corticosteroids, and allergen immunotherapy remains to be determined. Specific immunotherapy for latex allergy (either subcutaneous or sublingual immunotherapy) has been evaluated. However, the frequency and severity of side effects remain high so immunotherapy for patients with moderate to severe asthma is contraindicated.

ANGIOTENSIN-CONVERTING ENZYME INHIBITOR—INDUCED COUGH

Cough has become a well-recognized side effect of angiotensin-converting enzyme (ACE) inhibitor therapy. According to spontaneous reporting by patients, cough occurs in 1% to 10% of patients...
receiving ACE inhibitors, with a preponderance of females. In a retrospective analysis, 14.6% of women had cough compared with 6.0% of the men on ACE inhibitors. It is suggested that women have a lower cough threshold, resulting in their reporting this adverse effect more commonly than men. Studies specifically evaluating cough caused by ACE inhibitors report a prevalence of 19% to 25%, and patients receiving diuretics. Patients receiving ACE inhibitors had a 2.3 times greater likelihood of developing cough than a similar group of patients receiving diuretics. Patients with hyperreactive airways do not appear to be at greater risk. African Americans and Chinese have a higher incidence of cough. When different disease states were compared, 26% of patients with heart failure had ACE inhibitor—induced cough compared with 14% of those with hypertension. Cough can occur with all ACE inhibitors.

The cough is typically dry and nonproductive, persistent, and not paroxysmal. The severity of cough varies from a “tickle” to a debilitating cough with insomnia and vomiting. The cough can begin within 3 days or have a delayed onset of up to 12 months following initiation of ACE inhibitor therapy. The cough remits within 1 to 4 days of discontinuing therapy but (rarely) can last up to 4 weeks and recur with rechallenge. Patients should be given a 4-day withdrawal to determine if the cough is induced by ACE inhibitors. The chest radiograph is normal, as are pulmonary function tests (spirometry and diffusing capacity). Bronchial hyperreactivity, as measured by histamine and methacholine provocation, may be worsened in patients with underlying bronchial hyperreactivity such as asthma and chronic bronchitis. However, bronchial hyperreactivity is not induced in others. The cough reflex to capsaicin is enhanced but not to nebulized distilled water or citric acid.

The mechanism of ACE inhibitor—induced cough is still unknown. ACE is a nonspecific enzyme that also catalyzes the hydrolysis of bradykinin and substance P (see Chap. 19) that produce or facilitate inflammation and stimulate lung irritant receptors. ACE inhibitors may also induce cyclooxygenase to cause the production of prostaglandins. NSAIDs, benzonatate, inhaled bupivacaine, theophylline, baclofen, thromboxane A2 synthase inhibitor, and cromolyn sodium all have been used to suppress or inhibit ACE inhibitor—induced cough. The cough is generally unresponsive to cough suppressants or bronchodilator therapy. No long-term trials evaluating different treatment options for ACE inhibitor—induced cough exist. Cromolyn sodium may be considered first because it is the most studied agent and has minimal toxicity. The preferred therapy is withdrawal of the ACE inhibitor and replacement with an alternative antihypertensive agent. Owing to their decrease in ACE inhibitor—induced side effects, angiotensin II receptor antagonists are often recommended in place of an ACE inhibitor; however, there are rare reports of this agent inducing bronchospasm. The clinical trials suggest that angiotensin II receptor antagonists have the same incidence of cough as placebo. Furthermore, when angiotensin II receptor antagonists were compared with ACE inhibitors, cough occurred much less frequently. Reduction in the incidence of cough with angiotensin II receptor antagonists is likely caused by the lack of effect on clearance of bradykinin and substance P. The use of alternative therapies to treat ACE inhibitor—induced cough is generally not recommended.

**NARCOTIC-INDUCED PULMONARY EDEMA**

The most common drug-induced noncardiogenic pulmonary edema is produced by the narcotic analgesics (Table 36–4). Narcotic-induced pulmonary edema is associated most commonly with intravenous heroin use but also has occurred with morphine,
methadone, meperidine, and propoxyphene use. There have also been a few reported cases associated with the use of the opiate naltrexone and naloxone, a long-acting opioid antagonist. The mechanism is unknown but may be related to hypoxemia similar to the neurogenic pulmonary edema associated with cerebral tumors or trauma or a direct toxic effect on the alveolar capillary membrane. Initially thought to occur only with overdoses, most evidence now supports the theory that narcotic-induced pulmonary edema is an idiosyncratic reaction to moderate as well as high narcotic doses.

Patients with pulmonary edema may be comatose with depressed respirations or dyspnea and tachypnea. They may or may not have other signs of narcotic overdose. Symptomatology varies from cough and mild crepitations on auscultation with characteristic radiologic findings to severe cyanosis and hypoxemia, even with supplemental oxygen. Symptoms may appear within minutes of intravenous administration but may take up to 2 hours to occur, particularly following oral methadone. Hemodynamic studies in the first 24 hours have demonstrated normal pulmonary capillary wedge pressures in the presence of pulmonary edema.

Clinical symptoms generally improve within 24 to 48 hours, and radiologic clearing occurs in 2 to 5 days, but abnormalities in pulmonary function tests may persist for 10 to 12 weeks. Therapy consists of naloxone administration, supplemental oxygen, and ventilatory support if required. Mortality is less than 1%.

Cough has been reported with intravenous administration of fentanyl. A cohort of 1,311 adult patients undergoing elective surgery had 120 patients with vigorous cough within 20 seconds after administration of fentanyl. The cough was associated with young age and absence of cigarette smoking. Among anesthetic factors, it was associated with the absence of epidurally administered lidocaine and the absence of a priming dose of vecuronium. A history of asthma or COPD had no predictive effect. Further clinical trials are required to understand the mechanism of paradoxical cough with fentanyl and to identify the means to prevent it.

### OTHER DRUGS THAT CAUSE PULMONARY EDEMA

A paradoxical pulmonary edema has been reported in a few patients following hydrochlorothiazide ingestion but not any other thiazide diuretic. Acute pulmonary edema rarely has followed the injection of high concentrations of contrast medium into the pulmonary circulation during angiocardiography. Rare occurrences of pulmonary edema have followed the intravenous administration of bleomycin, cyclophosphamide, and vinblastine.

The selective β₂-adrenergic agonists terbutaline and ritodrine have been reported to induce pulmonary edema when used as tocolytics. This disorder commonly occurs 48 to 72 hours after tocolytic therapy. This has never occurred with their use in asthma patients, even in inadvertent overdosage. This reaction may result from excess fluid administration used to prevent the hypotension from β₂-mediated vasodilation or the particular hemodynamics of pregnancy. In a review of 330 patients who received tocolytic therapy and were monitored closely for their fluid status, no episode of pulmonary edema was reported.

Interleukin-2, a cytokine used alone or in combination with cytotoxic drugs, has been reported to induce pulmonary edema. Although other cytokines have been associated with pulmonary edema, the problem is most significant with interleukin-2. A weight gain of 2 kg has been reported after treatment with interleukin-2.

Pulmonary edema has occurred occasionally with salicylate overdoses. The serum salicylate concentrations are often greater than 45 mg/dL, and the patients have other signs of toxicity, although some cases have been associated with concentrations in the usual therapeutic range.

### PULMONARY EOSINOPHILIA

Pulmonary infiltrates with eosinophilia (Löffler syndrome) are associated with nitrofurantoin, para-aminosalicylic acid, methotrexate, sulfonamides, tetracycline, chlorpromazine, phenytoin, NSAIDs, and imipramine. The disorder is characterized by fever, nonproductive cough, dyspnea, cyanosis, bilateral pulmonary infiltrates, and eosinophilia in the blood. Lung biopsy has revealed perivasculitis with infiltration of eosinophils, macrophages, and proteinaceous edema fluid in the alveoli. The symptoms and eosinophilia generally respond rapidly to withdrawal of the offending drug.

Sulfonamides were first reported as causative agents in users of sulfanilamide vaginal cream. para-Aminosalicylic acid frequently produced the syndrome in tuberculosis patients being treated with this agent. There are nine reported cases associated with sulfasalazine use in inflammatory bowel disease. Nitrofurantoin-induced lung disorders appear to be more common in postmenopausal women. Lung reactions made up 43% of 921 adverse reactions to nitrofurantoin reported to the Swedish Adverse Drug Reaction Committee between 1966 and 1976. No apparent correlation exists between duration of drug exposure and severity or reversibility of the reaction. Most cases occur within 1 month of therapy. Typical symptoms include fever, tachypnea, dyspnea, dry cough, and, less commonly, pleuritic chest pain. Radiographic findings include bilateral interstitial infiltrates, predominant in the bases and pleural effusions 25% of the time. Although there are anecdotal reports that steroids are beneficial, the usual rapid improvement following discontinuation of the drugs brings the usefulness of steroids into question. Complete recovery usually occurs within 15 days of withdrawal.

F, frequent; I, infrequent; R, rare.
A few cases of pulmonary eosinophilia have been reported in asthmatics treated with cromolyn. The significance of this is unknown in light of the occasional spontaneous occurrence of pulmonary eosinophilia in asthmatic patients. Cases of acute pneumonitis and eosinophilia have been reported to occur with phenytoin and carbamazepine therapy. Patients have had other symptoms of hypersensitivity, including fever and rashes. The symptoms of dyspnea and cough subside following discontinuation of the drug.

**OXYGEN TOXICITY**

Because of the similarity to pulmonary fibrosis, oxygen-induced lung toxicity is reviewed briefly. More extensive reviews on this topic have been published.

The earliest manifestation of oxygen toxicity is substernal pleuritic pain from tracheobronchitis. The onset of toxicity follows an asymptomatic period and presents as cough, chest pain, and dyspnea. Early symptoms are usually masked in ventilator-dependent patients. The first noted physiologic change is a decrease in pulmonary compliance caused by reversible atelectasis. Then decreases in vital capacity occur, followed by progressive abnormalities in carbon monoxide diffusing capacity. Decreased inspiratory flow rates, reflected in the need for high inspiratory pressures in ventilator-dependent patients, occur as the fractional concentration of inspired oxygen requirement increases. The lungs become progressively stiffer as the ability to oxygenate becomes more compromised.

The fraction of inspired oxygen and duration of exposure are both important determinants of the severity of lung damage. Normal human volunteers can tolerate 100% oxygen at sea level for 24 to 48 hours with minimal to no damage. Oxygen concentrations of less than 50% are well tolerated even for extended periods. Inspired oxygen concentrations between 50% and 100% carry a substantial risk of lung damage, and the duration required is inversely proportional to the fraction of inspired oxygen. Underlying disease states may alter this relationship. Lung damage may not be lasting and may improve months to years after the exposure.

Oxygen-induced lung damage is generally separated into the acute exudative phase and the subacute or chronic proliferative phase. The acute phase consists of perivascular, peribronchiolar, interstitial, and alveolar edema with alveolar hemorrhage and necrosis of pulmonary endothelium and type I epithelial cells. The proliferative phase consists of resorption of the exudates and hyperplasia of interstitial and type II alveolar lining cells. Collagen and elastin deposition in the interstitium of alveolar walls then leads to thickening of the gas-exchange area and the fibrosis.

The biochemical mechanism of the tissue damage during hyperoxia is the increased production of highly reactive, partially reduced oxygen metabolites (Fig. 36–1). These oxidants are normally produced in small quantities during cellular respiration and include the superoxide anion, hydrogen peroxide, the hydroxyl radical, singlet oxygen, and hypochlorous acid. Oxygen free radicals are normally formed in phagocytic cells to kill invading microorganisms, but they are also toxic to normal cell components. The oxidants produce toxicity through destructive redox reactions with protein sulphydryl groups, membrane lipids, and nucleic acids.

The oxidants are products of normal cellular respiration that are normally counterbalanced by an antioxidant defense system that prevents tissue destruction. The antioxidants include superoxide dismutase, catalase, glutathione peroxidase, ceruloplasmin, and α-tocopherol (vitamin E). Antioxidants are ubiquitous in the body. Hyperoxia produces toxicity by overwhelming the antioxidant system. There is experimental evidence that a number of drugs and chemicals produce lung toxicity through increasing production of oxidants (e.g., bleomycin, cyclophosphamide, nitrofurantoin, and paraquat) and/or by inhibiting the antioxidant system (e.g., carmustine, cyclophosphamide, and nitrofurantoin).

**PULMONARY FIBROSIS**

A large number of drugs are associated with chronic pulmonary fibrosis with or without a preceding acute pneumonitis (Table 36–6). The cancer chemotherapeutic agents make up the largest group and have been the subject of numerous reviews.

F, frequent; I, infrequent; R, rare.
Although the mechanisms by which all the drugs produce pneumonia and fibrosis are not known, the clinical syndrome, pulmonary function abnormalities, and histopathology present a relatively homogeneous pattern. The histopathological picture closely resembles oxidant lung damage, and in some experimental cases, oxygen enhances the pulmonary injury. Although the terms pulmonary fibrosis or interstitial pneumonia have been used widely to describe pneumonia after bone marrow transplantation, in 1991, a National Institutes of Health workshop recommended that the term idiopathic pneumonia syndrome (IPS) should be used to avoid histopathological terms and to define the inherent heterogeneity of this disorder. IPS accounts for more than 40% of deaths related to bone marrow transplantation. Suggested causes of IPS include radiation or chemotherapy regimens prior to transplantation, graft-versus-host disease, unrecognized infections, and other inflammation-related lung injuries. IPS is characterized by dyspnea, hypoxemia, nonproductive cough, diffuse alveolar damage, and interstitial pneumonitis in the absence of lower respiratory infection. IPS has been reported early and late, up to 24 months after bone marrow transplantation. The lung damage following ingestion of the contact herbicide paraquat classically resembles hyperoxic lung damage. Hyperoxia accelerates the lung damage induced by paraquat. Lung toxicity from paraquat occurs following oral administration in humans and aerosol administration and inhalation in experimental animals. The pulmonary specificity of paraquat results in part from its active uptake into lung tissue. Paraquat readily accepts an electron from reduced nicotinamide-adenine dinucleotide phosphate and then is reoxidized rapidly, forming superoxide and other oxygen radicals. The toxicity may be a result of nicotinamide-adenine dinucleotide phosphate depletion (see Fig. 36–1) and/or excess oxygen free radical generation with lipid peroxidation. Treatment with exogenous superoxide dismutase has had limited and conflicting results.

A number of furans have been shown to produce oxidant injury to lungs. Occasionally, patients with acute nitrofurantoin lung toxicity will progress to a chronic reaction leading to fibrosis, and rarely, a patient may develop chronic toxicity without an antecedent acute reaction. Like paraquat, nitrofurantoin undergoes cyclic reduction and reoxidation that may produce superoxide radicals or deplete nicotinamide-adenine dinucleotide phosphate. In addition, nitrofurantoin inhibits glutathione reductase, an enzyme involved in the glutathione antioxidant system (see Fig. 36–1). Table 36–7 lists possible nondrug causes of pulmonary fibrosis.

### DRUGS ASSOCIATED WITH PULMONARY FIBROSIS

#### ANTINEOPLASTICS

A number of cancer chemotherapeutic agents produce pulmonary fibrosis. In an excellent review, six predisposing factors for the development of cytotoxic drug—induced pulmonary disease were described: (a) cumulative dose, (b) increased age, (c) concurrent or previous radiotherapy, (d) oxygen therapy, (e) other cytotoxic drug therapy, and (f) preexisting pulmonary disease. Drugs that are directly toxic to the lung would be expected to show a dose—response relationship. Dose—response relationships have been established for bleomycin, busulfan, and carmustine (BCNU). Bleomycin and busulfan exhibit threshold cumulative doses below which a very small percentage of patients exhibit toxicity, but carmustine shows a more linear relationship. Older patients appear to be more susceptible, possibly as a result of a decrease in the antioxidant defense system.

#### BLEOMYCIN

Bleomycin is the best-studied cytotoxic pulmonary toxin. Because of its lack of bone marrow suppression, pulmonary toxicity is the dose-limiting toxicity of bleomycin therapy. The incidence of bleomycin lung toxicity is approximately 4%, which may be

Excessive irradiation produces a pneumonitis and fibrosis thought to be caused by oxygen free radical formation. Evidence for synergistic toxicity with radiation exists for bleomycin, busulfan, and mitomycin. Hyperoxia has shown synergistic toxicity with bleomycin, cyclophosphamide, and mitomycin. Carmustine, mitomycin, cyclophosphamide, bleomycin, and methotrexate all appear to show increased lung toxicity when they are part of multiple-drug regimens.

#### NITROSOUREAS

BCNU is associated with the highest incidence of pulmonary toxicity (20% to 30%). The lung pathology generally resembles that produced by bleomycin and busulfan. Unique to BCNU is the finding of fibrosis in the absence of inflammatory infiltrates. BCNU preferentially inhibits glutathione reductase, the enzyme required to regenerate glutathione, thus reducing glutathione tissue stores. The patients present with dyspnea, tachypnea, and nonproductive cough that may begin within a month of initiation of therapy but may not develop for as long as 3 years. Most patients receiving BCNU develop fibrosis that may remain asymptomatic or become symptomatic any time up to 17 years after therapy. The cumulative dose has ranged from 580 to 2,100 mg/m². The disease is usually slowly progressive with a mortality rate from 15% to greater than 90% depending on the study and period of follow-up. In a retrospective study, the risk factors for development of IPS and prognostic factors for outcomes were evaluated in 94 patients with relapsed Hodgkin disease treated with BCNU containing high-dose chemotherapy and hematopoietic support. The risk factors for pulmonary fibrosis and mortality were female sex and dose of BCNU, with all deaths reported in those who received BCNU at doses of more than 475 mg/m². Rapid progression and death within a few days occur in a small percentage of patients. Corticosteroids do not appear to be effective in reducing damage. Other nitrosoureas, lomustine, and semustine have also been reported to produce lung damage in patients receiving unusually high doses.
affected by the following risk factors: bleomycin cumulative dose, age, high concentration of inspired oxygen, radiation therapy, and multidrug regimens, particularly those with cyclophosphamide.86 Age at the time of treatment with bleomycin may also be a risk factor; patients younger than 7 years of age at the time of receiving bleomycin therapy are more likely to develop pulmonary toxicity compared with older subjects.86 The cumulative dose above which the incidence of toxicity significantly increases is 450 to 500 units.77 However, rapidly fatal pulmonary toxicity has occurred with doses as low as 100 units.77

Experimentally, bleomycin generates superoxide anions, and the lung toxicity is increased by radiation and hyperoxia.77 Pretreatment with superoxide dismutase and catalase reduces toxicity in experimental animals.77 Bleomycin also oxidizes arachidonic acid, which may account for the marked inflammation. Bleomycin may also affect collagen deposition by its stimulation of fibroblast growth.77 Combination of bleomycin with other cytotoxic agents, particularly regimens containing cyclophosphamide, may predispose patients to pulmonary damage.

There are two distinct clinical patterns of bleomycin pulmonary toxicity. Chronic progressive fibrosis is the most common; acute hypersensitivity reactions occur infrequently. Patients present with cough and dyspnea. The first physiologic abnormality seen is a decreased diffusing capacity of carbon monoxide.77 Chest radiographs show a bibasilar reticular pattern, and gallium scans show marked uptake in the involved lung.77 Chest radiographic changes lag behind pulmonary function abnormalities. Spirometry tests before each bleomycin dose are not predictive of toxicity. The single-breath diffusing capacity of carbon monoxide is the most sensitive indicator of bleomycin-induced lung disease. Although it is not absolutely predictive, a drop of 20% or greater in the diffusing capacity of carbon monoxide is an indication for using alternative therapies.77 The prognosis of bleomycin lung toxicity has improved as a consequence of early detection, but the mortality rate is approximately 25%. Mild cases respond to discontinuation of bleomycin therapy.64 Corticosteroid therapy appears to be helpful in patients with acute pneumonitis, although there have been no controlled trials. Patients with chronic fibrosis are less likely to respond. Although corticosteroids have been used for a number of drug-induced pulmonary problems, a study in mice showing a potential for worsening of lung damage when administered early during the repair stage should sound a word of caution against their indiscriminate use.84

**MITOMYCIN**

Mitomycin is an alkylating antibiotic that produces pulmonary fibrosis at a frequency of 3% to 12%.77 The mechanism is unknown, but oxygen and radiation therapy appear to enhance the development of toxicity.77 The clinical presentation and symptoms are the same as for bleomycin. The mortality rate is approximately 50%. Early withdrawal of the drug and administration of corticosteroids appear to improve the outcome significantly.

**ALKYLATING AGENTS**

A number of alkylating agents are associated with pulmonary fibrosis (see Table 36–5). The incidence of clinical toxicity is around 4%, although subclinical damage is apparent in up to 46% of patients at autopsy. The mechanism of toxicity is unknown; however, epithelial cell damage that triggers the arachidonic acid inflammatory cascade may be the initiating event.77 The clinical presentation is insidious, with 4 years being the average duration of therapy before the onset of symptoms.77 Patients present with low-grade fever, weight loss, weakness, dyspnea, cough, and rales.77 Pulmonary function tests initially show abnormal diffusion capacity followed by a restrictive pattern (low vital capacity). The histopathologic findings are nonspecific. The prognosis is one of slow progression with a mean survival of 5 months following diagnosis.77 Although there is no direct dose-dependent correlation, patients receiving less than 500 mg of busulfan do not develop the syndrome without concomitant radiation or use of other pulmonary toxic chemotherapeutic agents.77 There are anecdotal reports of beneficial responses to corticosteroids, but no controlled studies have been done.

Cyclophosphamide infrequently produces pulmonary toxicity. More than 20 well-documented cases have been reported to date. In animal models, cyclophosphamide produces reactive oxygen radicals. High oxygen concentrations produce synergistic toxicity with cyclophosphamide. The duration of therapy before the onset of symptoms is highly variable, and there may be a delay of several months between the onset of symptoms and discontinuation of the drug.77 Cyclophosphamide may potentiate carcinust lung toxicity.77 Clinical symptoms usually consist of dyspnea on exertion, cough, and fever. Inspiratory crackles and the bibasilar reticular pattern typical of cytotoxic drug-induced radiographic changes are present. Histopathological changes are also nonspecific. Approximately 60% of patients recover. Corticosteroid therapy has been reported to be beneficial; however, death despite corticosteroid administration has also been reported.

Chlorambucil, melphalan, and uracil mustard are also associated with pulmonary fibrosis. Of the alkylating agents, only nitrogen mustard and thiopeta have not been reported to cause fibrotic pulmonary toxicity.77

**ANTIMETABOLITES**

Methotrexate was first reported to induce pulmonary toxicity in 1969.77 The pulmonary toxicity to methotrexate is unique in that discontinuation is not always necessary, and reinstitution of the drug may not produce recurrence of symptoms.6 Methotrexate pulmonary toxicity most commonly appears to result from hypersensitivity,71 and it can occur 3 or more years following methotrexate therapy.65 Age, sex, underlying pulmonary disease, duration of therapy, or smoking is not associated with an increased risk of pneumonitis with methotrexate.65 Serial pulmonary function tests did not help to identify pneumonitis in patients receiving methotrexate before the onset of clinical symptoms.81 Reductions in diffusing capacity of carbon monoxide and lung volumes are the most common manifestations of methotrexate lung toxicity.66 Pulmonary edema and eosinophilia are common, and fibrosis occurs in only 10% of the patients who develop acute pneumonitis.77 Systemic symptoms of chills, fever, and malaise are common before the onset of dyspnea, cough, and acute pleuritic chest pain. Methotrexate is also associated with granuloma formation.77

The prognosis of methotrexate-induced pulmonary toxicity is good, with a 1% or less mortality rate.25 Pulmonary toxicity has followed intrathecal as well as oral administration and has occurred after single doses as well as long-term daily and intermittent administration.77 Pneumonitis has been reported to occur up to 4 weeks following discontinuation of therapy.77 Numerous anecdotal reports have claimed dramatic benefit from corticosteroid therapy. It is unknown whether intermittent (weekly) dosing, as is done for rheumatoid arthritis, decreases the risk of methotrexate-induced pulmonary toxicity because pneumonitis has occurred with this form of dosing.

Rarely, azathioprine and its major metabolite 6-mercaptopurine have been reported to produce an acute restrictive lung disease. Procarbazine, a methylhydrazine associated more commonly with Löffler syndrome, rarely has been associated with pulmonary fibrosis.71 The vinca alkaloids vinblastine and vindesine have been
reported to produce severe respiratory toxicity in association with mitomycin. The incidence with the combination is 39% and may represent a true synergistic effect between these agents.77

NONCYTOTOXIC DRUGS

Pulmonary fibrosis associated with the ganglionic-blocking agent hexamethonium was first reported in 1954 (see Table 36–6).6 Pulmonary fibrosis, pleural effusions, and pleuritic pain 5 to 16 weeks following institution of therapy.66 Pulmonary function tests show a restrictive defect, and patients generally have an eosinophilia. The reactions improve on discontinuation of the drug and recurr promptly on reexposure. The pulmonary deficit may not resolve completely.

AMIODARONE

Amiodarone, a benzoofuran derivative, produces pulmonary fibrosis when used for supraventricular and ventricular arrhythmias (see Table 36–6).66 The duration of amiodarone therapy before the onset of symptoms has ranged from 4 weeks to 6 years.67,68,69 The estimated incidence is 1 in 1,000 to 2,000 treated patients per year.66 Routine spirometry does not appear to be predictive of patients at risk.67 Carbon monoxide diffusing capacity studies are sensitive indicators of amiodarone pulmonary toxicity but have only a 21% positive predictive value.67 Clinical findings include exertional dyspnea, nonproductive cough, weight loss, and occasionally low-grade fever.67,68,69 Radiographic changes are nondiagnostic and consist of diffuse bilateral interstitial changes consistent with a pneumonitis. Pulmonary function abnormalities include hypoxia, restrictive changes, and diffusion abnormalities.

The mechanism of amiodarone-induced pulmonary toxicity is multifactorial. Amiodarone and its metabolite can damage lung tissue directly by a cytotoxic process or indirectly by immunologic reactions.68 Amiodarone is an amphiphilic molecule that contains both a highly apolar aromatic ring system and a polar side chain with a positively charged nitrogen atom.68 Amphiphilic drugs characteristically produce a phospholipid storage disorder in the lungs of experimental animals and humans.68 Chlorthalidone, an anorectic, is the prototype amphiphilic compound. The mechanism is currently believed to be the inhibition of lysosomal phospholipases.68 The inflammation and fibrosis are thought to be a late finding resulting from nonspecific inflammation following the breakdown of phospholipid-laden macrophages.68

In a review of 39 cases, 9 patients died, and the remaining 30 patients had resolution of abnormalities after withdrawal of the drug.66 Some patients have had resolution with lowering of the dosage, and therapy has been re instituted at lower doses without problems in others. Of the patients who died, one half had received corticosteroids. There are reports of a protective effect with prophylactic corticosteroids and other reports of patients developing amiodarone lung toxicity while on corticosteroids.66 At this time, any benefit of corticosteroids is unclear because most patients improve after stopping the drug.

MISCELLANEOUS PULMONARY TOXICITY

Drugs may produce serious pulmonary toxicity as part of a more generalized disorder. The pleural thickening, effusions, and fibrosis that occur as an extension of the retroperitoneal fibrotic reactions of methysergide and practolol or as part of a drug-induced lupus syndrome are the most common examples (Table 36–8).

Pleural and pulmonary fibrosis has been reported in one patient taking pindolol, a β-blocker structurally similar to practolol, an agent known to produce fibrosis.67 Acute pleuritis with pleural effusions and fibrosis is a prominent manifestation of drug-induced lupus syndrome. Procainamide is associated with the largest number of pulmonary reactions, with 46% of patients with the lupus syndrome developing pulmonary complications.66 Symptoms include pleuritic pain and fever with muscle and joint pain. Chest radiographs show bilateral pleural effusions and linear atelectasis. Patients have a positive antinuclear antibody test. Symptoms usually resolve within 6 weeks of drug withdrawal.66

Hydralazine is the next most common cause of lupus syndrome. Most patients who develop pleuropulmonary manifestations have antecedent symptoms of generalized lupus.66 Other drugs that produce the lupus syndrome include isoniazid and phenytoin. Phenytoin can also produce hilar lymphadenopathy as part of a generalized pseudolymphoma or lymphadenopathy syndrome.66

MONITORING THERAPEUTIC OUTCOMES

Monitoring for drug-induced pulmonary diseases consists primarily of having a high index of suspicion that a particular syndrome may be drug induced. Most hypersensitivity or allergic reactions (bronchospasm) occur rapidly, within the first 2 weeks of therapy with the offending agent, and reverse rapidly with appropriate therapy (e.g., withdrawal of the offending agent and administration of corticosteroids and bronchodilators). Dyspnea associated with Löffler syndrome and acute pulmonary edema syndromes also improve rapidly in 1 to 2 days. However, some residual defect in diffusion capacity and the roentgenogram may persist for a few weeks. It is probably unnecessary to do follow-up spirometry or diffusion capacity determinations in these patients unless there is some concern that the syndrome will progress to pulmonary fibrosis (through the use of bleomycin or nitrofurantoin).

The routine monitoring of patients receiving known pulmonary toxins with dose-dependent toxicity such as amiodarone, bleomycin, or carmustine is still controversial. For chronic fibrosis, the diffusing capacity of carbon monoxide is the most sensitive test and may be useful in patients receiving bleomycin for detecting and preventing further deterioration of lung function with continued administration. Carmustine lung toxicity may be delayed up to 10 years following administration, and routine monitoring has not proved preventive. Monitoring patients receiving amiodarone in doses greater than 400 mg/day every 4 to 6 months may prove useful in detecting early disease that requires lowering the amiodarone or stopping the drug. Because there is no evidence of a cumulative dose effect once it has been established that the patient can tolerate the elevated dose, continued routine monitoring past the first year is unnecessary.

KEY CONCEPTS

1. Good nutrition with appropriate pancreatic enzyme and vitamin supplementation are essential in the management of cystic fibrosis.

2. Altered pharmacokinetics of cystic fibrosis patients can impact the dosing and clearance of pharmacologic therapy.

3. Airway clearance and antiinflammatory therapies are key components to improve pulmonary health in cystic fibrosis patients.

4. Antipseudomonal agents are the cornerstone of antibiotic therapy for chronic lung infections in the cystic fibrosis patient.

“Woe to that child which when kissed on the forehead tastes salty. He is bewitched and soon must die.” This European adage accurately describes the fate of an individual diagnosed with cystic fibrosis during ancient times.¹

Cystic fibrosis (CF) is a disease state resulting from a dysfunction in the cystic fibrosis transmembrane receptor (CFTR). It is the most common life-limiting disorder in the white population, with an incidence of 1 in 2,000 to 4,000 live births and a prevalence of 30,000 affected individuals in the United States.² – ⁷

Currently with care, affected individuals have an expected life span of 36 years. Multiple organ systems are affected in CF individuals; especially, the lungs, the digestive system, and the reproductive organs. Mortality is most commonly due to chronic organ damage or resistant pulmonary infections.⁸

The pharmacist plays an essential role in the development and management of a pharmacotherapeutic care plan for the CF patient.

EPIDEMIOLOGY

CF is an autosomal recessive disease occurring in approximately 1 in 3,500 newborns. In the 1970s, patients only survived into their teen years. By 2006, progress in care had extended survival to 36 years. Institution of care at a young age impacts long-term survival; hence, timing of diagnosis and recognition of signs and symptoms is crucial.⁹ – ¹⁷

Although CF occurs in all ethnicities, other ethnicities besides the white population display lower frequencies: 1 in 9,200 Hispanic Americans, 1 in 10,900 Native Americans, 1 in 15,000 African Americans, and 1 in 31,000 Asians. The carrier frequency is 1 in 28 for North American white populations, 1 in 29 Ashkenazi Jews, and 1 in 60 African Americans.²

ETIOLOGY

The cause of CF is due to a mutation of the CFTR gene. Extensive genetic studies have increased awareness regarding the large spectrum of mutations in the CF population. Over 15,000 mutations have been identified, however, typical panels screen for only 30 of them. The most common mutation identified in CF patients is ΔF508.³

Cystic fibrosis is an autosomal recessive disease, in which one mutation present on each allele of the CFTR gene results in presentation of the disease. The presentation of a mutation on only one allele of the CFTR gene will prevent the full expression of CF. Genetic studies have increased the understanding of genotype—phenotype relationships. Various mutations on the CFTR gene can result in various pathologies from primary lung disease to minor gastrointestinal (GI) involvement.³

PATHOPHYSIOLOGY

In order to treat CF successfully, a good understanding of the disease’s underlying mechanism of action is crucial. It is well established that gene mutations cause an abnormality in the cystic fibrosis transmembrane conductance regulator. This initiates the sequence of events responsible for the manifestations of CF. Mucosal obstruction occurs in the distal airways of the lung and submucosal glands, which express the CFTR. The CFTR also performs numerous cellular functions, including the regulation of chloride transport across the cell membrane. Studies in genotype—phenotype relationships have shown that an abnormality on the CFTR contributes to the expression of other gene proteins involved with inflammatory responses, ion transport, and cell signaling. These various expressions result in differences in clinical severity among patients with the same mutations on the CFTR.³, ⁸ – ¹¹

Under normal conditions, the CFTR helps regulate ion transport and salt homeostasis in the sweat glands. Normally, the sodium ion is followed by the chloride ion and is reabsorbed from the lumen by the CFTR and apical sodium channels. As a result of the CFTR’s malfunction in CF patients, chloride fails to be reabsorbed, which impacts the sodium ion reabsorption as well. This failed process produces sweat that contains high levels of salt. The end point of this process is a highly negatively charged lumen, which leads to an increased salt content in the sweat gland. This is also known as the transepithelial potential difference, which is 2 to 3 times as great in CF patients, as
Respiratory Disorders

the potential difference in patients without the disease. These pro-

FIGURE 37-1. Mechanism of underlying elevated sodium chloride levels in the sweat of patients with cystic fibrosis. Sweat ducts (panel A) in patients with cystic fibrosis differ from those in people without the disease in the ability to reabsorb chloride before the emergence of sweat on the surface of the skin. A major pathway for Cl− absorption is through CFTR, situated within luminal plasma membranes of cells lining the duct (i.e., on the apical, or mucosal, cell surface) (panel B). Diminished chloride reab-
sorption in the setting of continued sodium uptake leads to an elevated transepithelial potential difference across the wall of the sweat duct, and the lumen becomes more negatively charged because of a failure to reabsorb chloride (panel C). The result is that total sodium chloride flux is markedly decreased, leading to increased salt content. The thickness of the arrows corresponds to the degree of movement of ions.10 (Rowe SM, Miller S, Sorscher EJ. Cystic fibrosis. N Engl J Med 2005;352(19):1992–2001. CFTR

Sinus and pulmonary infections, pancreatic insufficiency, and elevated sweat chloride levels. Patients with nonclassic CF have one mutation present, therefore retaining partial function of the CFTR and maintaining appropriate pancreatic function. (Fig. 37–3.)

CLINICAL PRESENTATION

In the classic presentation of CF, there are two mutations present (Table 37–1). The patients show signs and symptoms of chronic sinus and pulmonary infections, pancreatic insufficiency, and elevated sweat chloride levels. Patients with nonclassic CF have one mutation present, therefore retaining partial function of the CFTR and maintaining appropriate pancreatic function. (Fig. 37–3.)

SINUS AND PULMONARY PRESENTATION

CF patients will usually experience chronic infections and frequently develop polyps in the sinus cavity. Daily symptomatology includes shortness of breath and cough, with sputum production. A common finding in radiology chest films is a flat diaphragm with an increased chest diameter and air trapping. Pulmonary function tests will reflect a decrease in forced expiratory volume in 1 second (FEV1). Older patients will experience digital clubbing, a deformity of the fingers and fingernails often associated with chronic hypoxia.

Bacterial growth in the lungs will often drive CF patients to a state of exacerbation, resulting in increased cough, a reduction in pulmonary function, and increased sputum production with a change in color.

GASTROINTESTINAL SYSTEM PRESENTATION

Newborns may present with meconium ileus, which is considered diagnostic of CF. Infants and small children will show an increase in frequency of small stools. Typically, steatorrhea, or greasy stools, is present and can lead to a failure to thrive, resulting in malnutrition. Older patients may experience constipation, abdominal cramping, and flatulence. This presentation is due to the obstruction of the pancreatic ducts and intestinal tract and their inability to digest essential nutrients. Patients with nonclassic CF will mostly maintain adequate pancreatic function and the ability to digest and absorb nutrients.

Pancreatic malfunction can also lead to an insulin deficiency, which is often a later finding detected by a loss in weight, an increase in blood glucose levels, and a failed oral glucose tolerance test (OGTT).

REPRODUCTIVE PRESENTATION

As patients reach adolescent and adult ages, tests may show azoo-
sperma due to blockage of or the congenital bilateral absence of the vas deferens. Females may experience reduced fertility as cervi-
cal fluids have lower water content and decreased thinning during ovulation.9,15–16

DIAGNOSIS

CF newborn screening is required in all states as of 2010.17 Depending on the state, this may include immunoreactive trypsin (IRT) screening and/or DNA analysis for genetic mutations. Abnormal values are followed up with sweat testing. The quanti-
titative pilocarpine iontophoresis sweat test (QPIT) came about due to the risk of hyperpyrexia associated with older methods that utilized plastic body bags to make patients sweat. QPIT uses only a small area on the forearm, which is then stimulated to secrete sweat through the skin by iontophoresis of pilocarpine. Sweat from the stimulated area is then collected and analyzed for chloride content. Chloride concentrations are quantified as: normal: ≤39 mmol/L; intermediate: 40 to 59 mmol/L; abnormal: ≥60 mmol/L. Values ≥60 mmol/L are consistently diagnostic of CF. It is suggested that samples from two sites will increase the reliability of the diagnosis.27 (Fig. 37–4).

DESIRED OUTCOMES

Pharmacists play a vital role in assisting patients to reach the follow-
ing goals, both long-term and short-term. Since CF affects multiple
organ systems, there are several therapeutic goals that must be addressed for each system.⁴

**SINOPULMONARY**

- Prevent and treat sinusitis.
- Increase FEV₁ and promote optimal pulmonary function tests and prevent pulmonary exacerbations.
- Promote effective airway clearance by providing counseling on use of appropriate medications and chest physiotherapy.
- Prevent and treat colonization of the lungs with pathogens.
- Prevent and treat acute exacerbations.

**GASTROINTESTINAL**

- Control pancreatic insufficiency by providing adequate enzyme supplementation.
- Optimize growth and nutritional status.
- Promote healthy bowel habits.
- Maintain normal vitamin levels.

**REPRODUCTION**

- Provide mutation analysis with appropriate genetic counseling at the time of diagnosis and periodically thereafter.
Cystic Fibrosis Foundation Diagnosis Criteria and Clinical Presentation

A. Meets one or more of the following clinical features associated with the CF phenotype plus:
   a. Two CF mutations
   b. Two positive QPIT results
   c. An abnormal transepithelial potential difference value
B. The following are typical phenotypes associated with CF:
   a. Chronic sinopulmonary disease
      i. Persistent colonization/infection with pathogens typical of CF lung disease
      ii. Endobronchial disease manifested by
         1. Cough and sputum production
         2. Wheeze and air trapping
         3. Radiographic abnormalities
         4. Evidence of obstruction on pulmonary function test
         5. Digital clubbing
   b. Gastrointestinal/nutritional abnormalities
      i. Intestinal abnormalities
         1. Meconium ileus
         2. Exocrine pancreatic insufficiency
         3. Distal intestinal obstruction syndrome
         4. Rectal prolapse
         5. Recurrent pancreatitis
      ii. Chronic hepatobiliary disease manifested by clinical and/or laboratory evidence of
         1. Focal biliary cirrhosis
         2. Multilobar cirrhosis
      iii. Failure to thrive
      iv. Hypoproteinemia-edema
      v. Fat-soluble vitamin deficiencies
   c. Obstructive azoospermia in males
   d. Salt-loss syndromes
      i. Acute salt depletion
      ii. Chronic metabolic alkalosis
   e. CF in a first degree relative

PSYCHOSOCIAL

- Advocate activity in school and the workplace.
- Encourage compliance with pharmacologic and nonpharmacologic therapies in order to help prolong CF patient’s lives.

NUTRITION

In healthy individuals, the pancreas is vital to the absorption and digestion of essential nutrients for the body’s growth and function. In pancreatic-insufficient CF individuals, the resulting inability to absorb these nutrients may lead to malnourishment. The focus of treatment lies in achieving and maintaining normal weight for adults and normal growth patterns for children. This is mostly achieved by managing GI and pulmonary symptoms, monitoring nutrient and energy intakes, and addressing psychosocial and financial issues. Numerous population-based studies have provided strong evidence to support optimization of nutritional status, due to its association with an improved pulmonary status. The Cystic Fibrosis Foundation, therefore, recommends that both children and adults maintain normal nutritional status in an effort to promote, healthy pulmonary function, including a better FEV1, and an increase in survival.

To help meet this desired outcome, the Cystic Fibrosis Foundation recommends energy intakes greater than the standard for the general population to support weight gain and maintenance in children over 2 years and in adults. Trial evidence gathered from population-based studies has shown that energy intakes of 110% to 200% compared to the general health population intakes yield improved nutritional status in CF individuals. The Cystic Fibrosis Foundation has also established consensus-based assessment parameters to monitor nutritional status in CF individuals. These parameters and goals are listed under Table 37–2. In order to achieve these goals, pancreatic enzyme replacement therapy (PERT) is utilized to improve fat absorption due to pancreatic insufficiency. For patients who consistently fail to meet weight requirements, the clinician must consider the use of nutritional supplements that may be given orally or enterally via a percutaneous endoscopic gastrostomy tube (PEG).

PERT has been proven both safe and efficacious in improving nutritional status in CF patients and is recommended in addition to adequate dietary intake. Consensus-based guidelines have established a dose of 500 to 2,500 lipase units/kg of body weight per meal; or 10,000 units/kg/day; or 4,000 units/g of dietary fat per day. Generic enzyme supplements are not bioequivalent; therefore, the Cystic Fibrosis Foundation does not recommend their use.

Until recently, pancreatic enzymes were considered nutritional supplements and were not under the Food and Drug Administration (FDA) jurisdiction. New regulations required all pancreatic enzymes to obtain FDA approval by April 28th, 2010. To date, Creon®, and Zenpep®, and Pancreaze™ have been the only FDA approved preparations. Table 37–3 shows currently used enzyme preparations.18–39

Most preparations are capsules containing enteric-coated microspheres or enteric-coated tablets designed to withstand the acidic environment in the stomach allowing for absorption in the small intestine. Frequently CF patients require the addition of histamine receptor antagonists or proton pump inhibitors in order to create an alkaline environment in the intestine. Enteric-coated capsules should not be crushed but may be opened and mixed with nonalkaline food. However, if allowed to sit in food for a prolonged amount of time, the enteric coating will be lost and enzymes will be inactivated. Enzymes are administered prior to meals and snacks.40

Patients dosed beyond the recommended guidelines may develop fibrosing colonopathy, which leads to colonic strictures. This condition should be considered for individuals who have evidence of obstruction, bloody diarrhea, or ascites, as well as for patients who have a combination of abdominal pain, ongoing diarrhea and/or poor weight gain. Risk factors for fibrosing colonopathy include: age <12 years; enzyme dosage >6,000 lipase units/kg/meal for more than 6 months; history of meconium ileus or distal intestinal obstruction syndrome (DIOS); history of any intestinal surgery; and inflammatory bowel disease.

Patients who experience fibrosing colonopathy are treated by reducing the dose of enzyme supplements, or with oral laxatives and/or enemas, all of which have been proven effective. More severe cases may require surgical intervention.41

BONE HEALTH AND VITAMIN SUPPLEMENTATION

Increased longevity in CF patients has revealed bone disease as an emerging complication. Many studies have observed that 50% to 75% of CF adults have low bone density and increased rates of fractures. CF patients are especially at risk as a result of several contributing factors: malabsorption of vitamin D, poor nutritional status, physical inactivity, glucocorticoid therapy, delayed pubertal maturation, and early hypogonadism. Increased bone resorption and decreased bone formation are likely stimulated by elevated serum cytokine levels triggered by chronic pulmonary inflammation. Additionally, chronic infections lead to bone loss in patients.
Cystic Fibrosis

CHAPTER 37

Airway Clearance Therapy

Choosing a particular ACT routine for a patient is based on the patient’s needs. There is no consensus on the optimal method of ACT. The regimen, including duration or number of treatments per day, may be changed in response to acute illness or exacerbations.

Chest percussion was originally performed by hand, with a cupped hand pounding on the chest, which generates percussion or vibration. Currently, the most convenient method is the use of a percussion vest. Aerobic exercise is also effective and recommended for improved airway clearance.

The recommended sequence of clearance therapy or “pulmonary toilet” regimen is as follows (note that these therapies are recommended for individuals ≥6 years of age and are administered concurrently with percussion therapy):

1. Bronchodilator: Albuterol is commonly used for this indication. It helps open up the airways and prevents bronchospasm.
2. Hypertonic saline (HyperSal™): It hydrates the airway mucus and facilitates mucociliary function.
3. Dornase alfa (Pulmozyme®): Enzyme that cleaves extracellular DNA, which results in decreased viscosity of mucus.
4. Aerosolized antibiotics [tobramycin (TOBI®)]: If this therapy is indicated based on severity of lung disease and sputum cultures, it is administered after the CF patient completes percussion therapy.

PULMONARY HEALTH AND TREATMENT

One of the fundamentals of pulmonary care in CF patients is airway clearance. CF patients, in general, have impaired mucociliary clearance that results in thick sputum, predisposing them to chronic infections and inflammation. Effective airway clearance involves the use of a bronchodilator, a mucolytic medication, and chest percussion. It is recommended that airway clearance therapy (ACT) be initiated within the first few months of life (Table 37–4).

Choosing a particular ACT routine for a patient is based on the patient’s needs. There is no consensus on the optimal method of ACT. The regimen, including duration or number of treatments per day, may be changed in response to acute illness or exacerbations.

Chest percussion was originally performed by hand, with a cupped hand pounding on the chest, which generates percussion or vibration. Currently, the most convenient method is the use of a percussion vest. Aerobic exercise is also effective and recommended for improved airway clearance.

The recommended sequence of clearance therapy or “pulmonary toilet” regimen is as follows (note that these therapies are recommended for individuals ≥6 years of age and are administered concurrently with percussion therapy):

1. Bronchodilator: Albuterol is commonly used for this indication. It helps open up the airways and prevents bronchospasm.
2. Hypertonic saline (HyperSal™): It hydrates the airway mucus and facilitates mucociliary function.
3. Dornase alfa (Pulmozyme®): Enzyme that cleaves extracellular DNA, which results in decreased viscosity of mucus.
4. Aerosolized antibiotics [tobramycin (TOBI®)]: If this therapy is indicated based on severity of lung disease and sputum cultures, it is administered after the CF patient completes percussion therapy.

Regardless of pancreatic sufficiency, Pancreatic insufficient CF patients have the inability to absorb fat-soluble vitamins A, D, E, and K. Decreased calcium absorption and intake can also compound this problem. As bone disease progresses, this can lead to exclusion from lung transplantation, which is often a life-saving operation for individuals with CF.

Appropriate bone density monitoring for CF patients requires a bone density scan in addition to obtaining levels of fat-soluble vitamins periodically. Special multivitamin formulations contain high amounts of fat-soluble vitamins designed to deliver the appropriate doses required. Even with these precautions, adequate vitamin D levels may be difficult to maintain due to altered absorption, reduced fat mass, and minimal exposure to sunlight. Medical management of CF patients can also contribute to bone disease by the administration of glucocorticoids, post-transplant immunosuppressant therapies, and antibiotic therapies that require protection from sunlight exposure.

Pulmonary and Gastrointestinal Health

CF patients have a variety of pulmonary and gastrointestinal health issues. Pancreatic insufficiency, chronic sinusitis, pancreatic exocrine insufficiency, meconium ileus, and sweat chloride values are some of the findings in classic and nonclassic cystic fibrosis. These findings can help in the diagnosis and management of CF patients.

FIGURE 37-3. Classic and nonclassic cystic fibrosis. The findings in classic cystic fibrosis are shown on the left-hand side, and those of nonclassic cystic fibrosis on the right-hand side. Patients with nonclassic cystic fibrosis have better nutritional status and better overall survival. Although the lung disease is variable, patients with nonclassic cystic fibrosis usually have late-onset or more slowly progressive lung disease. Sweat-gland function, as evidenced by the sweat chloride test, is abnormal but not to the extent noted in classic cystic fibrosis. Pancreatitis may occur in patients with nonclassic disease. However, chronic sinusitis and obstructive azoospermia occur in both groups of patients. On the basis of these findings, one can infer that mutations in CFTR, perhaps coupled with other genetic or environmental factors, may confer a predisposition to sinusitis, pancreatitis, or congenital bilateral absence of the vas deferens (azoospermia) in the general population.

Bronchodilator therapy is recommended for patients ≥6 years of age who demonstrate bronchiole hyperresponsiveness or a bronchodilator response. Chronic use of bronchodilator therapy is recommended to improve lung function by enhancing mucociliary action. 52–53

Inhaled hypertonic saline is a novel agent used for the treatment of CF. Hypertonic saline is recommended for patients ≥6 years of age. A study conducted in Australia showed that CF patients who surfed had better pulmonary outcomes than patients who did not surf. 54–55 Researchers believed that the inhalation of ocean water helped to improve FEV₁ in CF patients that surfed. In this study, 24 patients were randomly assigned to receive a daily treatment of 7% hypertonic saline with or without pretreatment of a control. Clearance and pulmonary function were measured during a 14-day period. Results showed significant improvement in FEV₁ and forced vital capacity (FVC), as well as improvement of respiratory symptoms in hypertonic saline patients. The study also demonstrated these patients were able to sustain mucus clearance for >8 hours. Other studies assessing the use of hypertonic saline have supported this study, showing an improvement in lung function and a 56% reduction in exacerbations. 52–56

Dornase alfa (Pulmozyme®) is also recommended in all patients ≥6 years of age and is strongly recommended for patients with moderate to severe lung disease to improve lung function and reduce exacerbations. Three randomized controlled trials and a crossover trial involving 520 patients were conducted. Study results showed improvement in FEV₁ by 3.2% and a reduction in exacerbations. 52,57–58

**TABLE 37-2** Cystic Fibrosis Foundation Nutritional Assessment Parameters and Recommendations

- Age-appropriate BMI method should be utilized to assess weight and height.
- Better FEV₁ status at about 80% predicted or above was associated with BMI % at 50th percentile or higher.
- For children and adolescents aged 2 to 20 years, the CF Foundation recommends that weight-for-stature assessment use the BMI percentile method and that children and adolescents maintain a BMI at or above the 50th percentile.
- For children diagnosed before age 2 years, the CF Foundation recommends that children reach a weight-for-length status of 50th percentile by age 2 years.
- For adults aged 20 years and older, the CF Foundation recommends that weight-for-stature assessment use the BMI method and that women maintain a BMI ≥22, and men maintain a BMI ≥23.
- For adults aged 20 years and older, the CF Foundation recommends that unintentional weight loss be avoided. When encountered in patient care, unintentional weight loss should be evaluated in the context of the patient’s usual weight and health status.

ANTIINFLAMMATORY THERAPIES

Pulmonary inflammation begins early in life, as shown by the predominance of proinflammatory mediators that can be seen on bronchiolar lavage. A normal inflammatory response to bacteria becomes pathologic in CF patients who have both a prolonged and exaggerated reaction. Treatment of this inflammatory response is crucial to treating the CF patient.

Antiinflammatory therapies must address the neutrophil response and inhaled therapies will target the endobronchial location, which is the site of inflammation. Using medications that terminate the inflammatory process may be effective. Airway clearance and anti-infectious biotics will help control the inflammatory stimulation. Steroids and anti-inflammatory agents are under investigation, but larger studies are needed before they become recommended therapies. 52,53,63–64

Infected CF patients often develop acute pulmonary exacerbations, are chronically infected with  P. aeruginosa, or require prevention of chronic  P. aeruginosa infection. A major disadvantage of treatment in CF patients is that pathogens are not fully eradicated from the airways and will often develop resistance. Unfortunately, this limits antimicrobial selection and can contribute to deterioration of pulmonary function.

Studies with macrolides have shown an inhibition of the neutrophil migration and decrease in production of proinflammatory mediators. It is unclear at this point if the antiinflammatory effects of macrolides are a combination of antimicrobial and/or immunomodulator mechanisms of action. A study conducted in Japan first demonstrated the benefit of macrolides against  P. aeruginosa. Four randomized controlled trials have since demonstrated this effect with azithromycin (250 to 500 mg) given 3 times weekly, which has led to increased nutritional status and decreased pulmonary infections. Other treatments are under investigation.

INFECTION DISEASE

Antibiotic therapy plays two integral roles in the treatment of CF patients: improving pulmonary function and preventing pulmonary failure. Oral, intravenous, and aerosolized antibiotic formulations are indicated and utilized for patients who experience acute pulmonary exacerbations, are chronically infected with  P. aeruginosa, or require prevention of chronic  P. aeruginosa infection. A major disadvantage of treatment in CF patients is that pathogens are not fully eradicated from the airways and will often develop resistance. Unfortunately, this limits antimicrobial selection and can contribute to deterioration of pulmonary function.

Early in life, patients will routinely be colonized with  S. aureus and then later with  P. aeruginosa.

Prophylaxis for  S. aureus colonization is not recommended because in a 5- to 7-year study of cephalaxin prophylaxis in young CF children, although the outcomes were favorable with respect to decreased  S. aureus colonization, there was an increase in frequency of  P. aeruginosa infections. Ultimately, this study showed no significant improvement in health outcomes. 85,86

The finding of  P. aeruginosa on sputum culture is a predictor of morbidity and mortality. There are relatively few antibiotics available for the treatment of  P. aeruginosa. Antibiotics available include: extended-spectrum penicillins, select cephalosporins, select carbapenems, aztreonam, quinolones, colistimethate, and aminoglycosides. The only two mechanisms of action represented in this group are cell-wall destruction and inhibited cell-wall synthesis by ribosomal attachment. Standard practice is to combine

these two mechanisms for the best bactericidal results. It is not unusual for patients to have multiple organisms growing in their sputum. The clinician can review the quantitative sputum culture for both the organisms present and the amount or colony units grown. By targeting the organisms with the most numerous bacterial species called *Pseudomonas aeruginosa*. At this point, sputum cultures can be sent to specialized laboratories that will test combinations of antibiotics and report out any synergy results. Aerosolized antibiotics are directly deposited into the lung, providing concentrations that may overcome the standard measures of resistance.67

Other organisms that may be seen are *Alcaligenes*, *Stenotrophomonas*, *Mycobacteria*, *Aspergillus*, and *Burkholderia*. The importance of *Alcaligenes* as a pathogen is not well described. Originally only thought to have a prevalence of 2.7%, better lab testing and more studies have found infection rates closer to 8% in CF patients greater than 6 years old.68-71 *Stenotrophomonas* is intrinsically multidrug resistant and pathogenic. A risk factor for acquiring this organism may be broad spectrum antibiotic use (carbapenems and cephalosporins).72-73 Quite often this bacteria is misidentified and confirmatory testing may show *Burkholderia*. Prevalence in American CF patients is reported to be 8.4%; however, some centers report incidence to be as high as 25%.74-76

Treatment choices are trimethoprim-sulfamethoxazole or doxycycline. *Mycobacteria* have been reported with more frequency in the last 10 years. Species include *M. tuberculosis*, nontuberculosis *M. chelonei*, *M. fortuitum*, and *M. avium-intracellulare* (MAI). The impact of *Mycobacteria* in the CF patient is unclear. Caseating granulomas have been found in some patients with clinical disease, while other patients with nontuberculosis mycobacterium have shown no adverse consequences.77-80 *Aspergillus* species has a prevalence of 10% to 25% in American CF patients. During the TOBI trials, patients treated with aerosolized tobramycin appeared to be more at risk for colonization with *Aspergillus* than the placebo group. Although *Aspergillus* does not directly inhibit lung function, it may cause allergic bronchopulmonary aspergillosis, which is an immunologic mediated response to the presence of *Aspergillus* in the lungs.81-82 *B. cepacia* is now known to be a bacterial species called *genomovar*. Currently, up to 9 species have been identified. This organism is commonly misidentified as *P. aeruginosa* or *Stenotrophomonas*.

The two typical antimicrobial choices to treat *B. cepacia* are ceftazidime and sulfamethoxazole-trimethoprim. It is important to recognize the transmission of *B. cepacia* from patient to patient has been shown and therefore proper infection control precautions should be taken. *B. cepacia* is usually transmitted via droplet route.85-88

Although CF patients are not more susceptible to respiratory viral infections, the outcome of such illnesses may be more severe. Decline in pulmonary function can be directly related to the number of annual viral infections. Newborns diagnosed with CF should receive respiratory syncytial virus (RSV) prevention with Synagis*, a monoclonal antibody, for the first 2 years of life. Synagis* is usually dosed at 15 mg/kg intramuscularly once a month during the RSV season. All CF patients who are 6 months of age or older should receive the annual influenza vaccine.86-89

Tobramycin (TOBI®) is recommended in all patients ≥6 years of age, and is strongly recommended for patients with moderate to severe lung disease and *Pseudomonas* present in sputum cultures. Aerosolized antibiotics deliver drugs locally to the lung while decreasing the risk of systemic side effects. In 1998, the FDA approved TOBI® for treating bacterial lung infections in patients with CF. Routine monitoring of serum aminoglycoside levels is unnecessary for patients with normal renal function using approved doses. It is recommended that CF patients use a preservative-free formulation of aerosolized antibiotics to prevent occurrence of bronchospasm.90

Gellar et al describe the pharmacokinetics of inhaled TOBI®, specifically looking at sputum concentrations in CF patients receiving three cycles of routine TOBI® (i.e., 28 days on, 28 days off), 300 mg twice a day. The study followed 258 patients for 24 weeks, and showed that approximately 95% of patients achieved sputum concentrations of >25 times the MIC of *Pseudomonas* isolates. This confirmed that inhaled TOBI® can be efficacious in helping prevent the progression of lung disease. At 25 times the MIC, tobramycin has a bactericidal effect.91

PHARMACOKINETICS

CF patients are unique in respect to a larger volume of distribution and a faster rate of clearance. With a larger volume of distribution, patients may require larger antibiotic doses. Dosing intervals become shorter because drugs are eliminated faster. Critically ill patients may vary from their baseline function and require closer monitoring. However, as patients age, they tend to approach normal population parameters. Therapeutic drug monitoring and necessary dosage and regimen adjustments are critical to the successful treatment of CF patients.

Once daily dosing of aminoglycosides is preferred for ease of home care administration, and may actually work well in this setting. However, given the possibility of a shortened half-life, each patient’s unique pharmacokinetic parameters must be calculated to determine if once daily dosing is appropriate.95-97

REPRODUCTION

Fertility discussions with older CF patients may arise during clinic visits, and these conversations should include genetic counseling and options for contraception. Drug-drug interactions between oral contraceptive pills (OCPs) and antibiotics should be monitored. Studies have shown that OCP use in CF patients is safe and effective in comparison with other contraception methods. Patches may not reliably adhere to the skin as a result of increased sweat on the surface of the skin.

The issues surrounding the use of contraception among CF men are similar to those among the normal population. CF men should not assume they are infertile and should adhere to using protective measures in order to prevent unwanted pregnancy and the spread of sexually transmitted diseases. Should a CF male with a nonfunctioning vas deferens desire to become a biological parent, microsurgical epididymal aspiration of spermatozoa with intracytoplasmic sperm injection into the oocyte can be performed.96

DIABETES

As CF patients live longer, glucose intolerance and CF-related diabetes (CFRD) are common complications. Even though it shares features of type 1 and type 2 diabetes, CFRD is unique because it is influenced by factors specific to CF, including: insulin deficiency, undertreatment, chronic and acute infection, elevated energy expenditure, glucagon deficiency, malabsorption, abnormal intestinal transit time, and liver dysfunction.97 In comparison with the general CF population, patients with CFRD show a higher mortality rate. In a study of 448 patients, 60% of non-CFRD population and 25% of the CFRD population were alive at age 30. The average

onset of CFRD is between 18 and 21 years, with a slight female predominance and is more commonly seen in CF gene mutation ΔF508.98–102

A desired goal in this population is to control hyperglycemia and hypoglycemia in order to reduce acute and chronic diabetes complications. Because insulin deficiency is the hallmark of CFRD, insulin is the recommended medical treatment. Insulin regimens are individualized based on the patient’s lifestyle and circumstances. Exercise is encouraged because it can improve peripheral insulin sensitivity and have beneficial effects in overall health, pulmonary function, and well being.99–102

Oral antidiabetic agents have inconsistent results in literature, therefore, support for their use in therapy for CFRD patients is not recommended. Medications that help improve insulin sensitivity do not address the primary problem of insulin deficiency in CF. Metformin’s mechanism of action is to improve hepatic and peripheral insulin sensitivity; however, it is contraindicated for patients with hypoxia due to the risk of fatal lactic acidosis. Additionally, metformin’s multiple GI effects include anorexia, diarrhea, flatulence, and abdominal discomfort. Thiazolidinediones help to enhance peripheral insulin sensitivity, but there is serious potential for hepatic toxicity due to the underlying liver problems in CF patients. The use of acarbose is also discouraged due to its mechanism of action, which reduces postprandial glucose and insulin excursion by limiting intestinal absorption of glucose. This inhibits the energy absorption in malnourished individuals while causing diarrhea, anorexia, and abdominal discomfort. Sulfonylureas are being considered due to their ability to enhance insulin secretion by acting on a specific islet beta cell receptor, however, evidence has also shown that these agents bind and inhibit the CFTR. Use of sulfonylureas is not recommended at this time.99,103

SPECIAL POPULATIONS

PREGNANCY

As women with CF live longer, more choose to become pregnant. CF women considering pregnancy and their partners should both undergo genetic counseling. CF women who become pregnant are considered a high-risk pregnancy; therefore, several considerations should be addressed at the onset of and during pregnancy. At the beginning, both current medications and medications that might be used to treat exacerbations need to be considered. Several of these medications are classified as category C and may pose a potential harm to the fetus. These patients should also be screened and treated accordingly for CFRD.

Several complications that will arise during CF pregnancy include increases in minute ventilation, increased oxygen uptake, and increased blood volume and cardiac output. In a woman with severe lung disease, these changes can cause right-sided heart failure. Other pharmacotherapy issues that are seen in this population are altered pharmacokinetics and increased maintenance of nutritional and pulmonary health.

The addition of the fetus impacts the CF woman’s health by placing a strain on a precariously balanced state of being. The CF woman who chooses to breastfeed must take into account the additional nutritional requirement of approximately 500 kcal/day.16

PEdiATRICS

Education of the parents is emphasized in this population, concerning administration of pancreatic enzymes and infant
Respiratory Disorders

SECTION 3

TRANSLANT PATIENTS

Lung transplantation has become an option with a 5-year survival rate of approximately 50%. Criteria for selection of transplant candidates include not only an FEV₁ of <30%, but also gender, nutritional status, diabetic status, sputum microbiology, and number of pulmonary exacerbations. Factors affecting compliance to CF care and to immunosuppressant therapy may also be taken under consideration for candidacy.

NEW THERAPIES

Currently being studied are attempts to restore normal airway hydration, either by inhaled osmotic agents that bring water to the airway surface or by inhaled agents that may inhibit ion transport. One such agent is mannitol, which works by creating an osmotic gradient; this is being studied as a dried powder inhaler. Amiloride inhibits ion transport, but its short half-life limits its usefulness. Compounds with similar structures are also being studied for potential use.

Due to antibiotic resistance, new therapies for CF often focus on new antibiotics. Tobramycin inhaled powder (TIP) and inhaled aztreonam (AZLI) are both currently in phase 3 trials. TIP's advantage is that it is administered faster than TOBI®. AZLI uses a new nebulizer to also reduce treatment time. A new inhaled antibiotic, Arikace, is now in phase 2 trials. This liposomal amikacin penetrates into CF mucus and delivers high concentrations of the drug to the site of infection. Castron® (aztreonam powder) has recently received approval from the European commission. It will use the Altera® nebulizer, which will decrease administration time from 30 minutes to 3 minutes. This would significantly improve compliance and have a positive impact on quality of life in CF patients.

CLINICAL CONTROVERSIES

CF is a worldwide problem, with a variety of approaches toward treatment. Discussions regarding controversial methods are constantly being held while new therapies are tried. Due to the relatively small population of CF patients, any studies that are conducted are frequently small in number or do not accurately reflect this population. This makes it difficult to extrapolate and come to a consensus regarding therapy. Some of these controversies will be discussed.

Inhaled and/or oral N-acetylcysteine (NAC) is an antioxidant that may have some antiinflammatory effect. The CF Foundation does not recommend this therapy due to insufficient evidence; however, a few published studies have led some clinicians to utilize this therapy. To date, there is not enough information to identify an NAC dosing strategy that is tolerable.

Bisphosphonate therapy is being added to bone health regimens in both adult and pediatric patients. Pediatric CF trials with these medications have not been conducted, although adult CF trials indicated potential value. CF children will develop bone disease that forces clinicians to decide whether to utilize this controversial therapy. In adult CF patients, there have been a few studies assessing the use of injectable bisphosphonate. The use of intravenous pamidronate showed significant gains in bone mineral density (BMD), however there was a high incidence of adverse events, such as moderate-severe bone pain, fever, and phlebitis. Injectable formulations are useful to the CF population because they bypass the malabsorption issue. A once-a-week oral bisphosphonate trial is underway. There has been at least one promising adult study with oral alendronate; however, no study has been performed with risedronate.

Colistimethate (Colistin®) is an antibiotic commonly used to treat pseudomonal infections. It is available in the injectable form that can be diluted and nebulized. Reports show a high incidence of bronchospasm and decline of FEV₁ in CF patients, especially in those with underlying reactive airway disease. Administration via inhalation can also be problematic due to low surface tension resulting in foaming of the solution. Thus, the recommended dose is questionable, due to variable drug delivery. However, for patients with multiple-drug-resistant pseudonas, this may be the only alternative.

SOCIAL

The social worker is an integral part of the CF team, due to the complex social issues that surround CF patients. Maintaining health insurance is a lifelong problem for CF patients. The inability to pay for CF meds may often influence compliance. Life insurance and homeowners insurance may never be obtainable. Maintaining employment is difficult because some employers may penalize for frequent hospitalizations. Thus, many CF patients have low paying jobs without insurance coverage.

Building relationships and confiding in others about personal health issues can be intimidating and difficult for CF patients. Children do not have opportunities to engage in friendships with other CF children. Due to infection control guidelines, group settings are limited. Support groups, although available, are restricted to online discussions. The decision to marry and have children is complicated by an awareness of a shortened life span.

SUMMARY

Multidisciplinary care for CF patients should involve pulmonologists, gastroenterologists, pharmacists, social workers, respiratory therapists, and dieticians. Complexity of care requires good communication within the CF team. Although intravenous antibiotics have historically been a mainstay of therapy, recent focus has shifted to optimizing nutrition status and promoting effective pulmonary clearance. New treatment modalities such as inhaled antibiotics will necessitate greater involvement by pharmacists. As patients live longer, more issues that are social arise, and medical issues become more complex.

ABBREVIATIONS

ACT: airway clearance therapy
BMD: bone mineral density
BMI: body mass index

The patient history is key to evaluating gastrointestinal (GI) tract disorders and should include the problem onset, the setting in which it developed, and its presentation. Patient warning signs and alarm symptoms should be identified quickly and referral for further evaluation should be obtained in a prompt manner.

A complete physical examination should be performed, the severity and location of symptoms directing the focus of the examination.

Contrast agents barium sulfate and gastrografin allow evaluation of the hollow organs of the digestive tract for mucosally-based lesions as well as narrowing or strictures involving the GI tract.

The upper GI series involves radiographic visualization of the esophagus, stomach, and small intestine; whereas the lower GI series involves visualization of the colon and rectum.

Enteroclysis is used to evaluate the small bowel by introducing contrast agents by tube through the nose or mouth directly into the small intestine.

Trans-abdominal ultrasound, computed tomography, and magnetic resonance imaging provide images of the gallbladder, liver, pancreas, and abdominal wall.

Radionuclide imaging is sometimes useful to visualize and evaluate the liver, spleen, bile ducts, and gallbladder.

The endoscope, an illuminated optical instrument, remains the cornerstone of gastrointestinal diagnosis and most importantly therapy. Common examples of endoscopic procedures include esophagogastroduodenoscopy, colonoscopy, enteroscopy, endoscopic retrograde cholangiopancreatography, and endoscopic ultrasound.

Capsule endoscopy, a newer less invasive endoscopic technique, takes pictures of the GI tract in the assessment of the small bowel in particular.

Ambulatory esophageal pH measurement is an important diagnostic test for gastroesophageal reflux disease and is often performed in conjunction with upper endoscopy. Most systems today are completely wireless and patient friendly.

Multichannel intraluminal impedance and pH monitoring combines acid exposure with impedance changes in resistant flow to aid the diagnosis of reflux in patients receiving a proton pump inhibitor and other antisecretory medications.

The gastrointestinal (GI) tract is composed of organs and tissues that have diverse forms and functions. It includes the esophagus, stomach, small intestine, large intestine, colon, rectum, gallbladder, liver, and pancreas. Despite the rapid proliferation of technology for the diagnosis of digestive diseases, the patient history and physical examination remain important for initial assessment, triage, and direction of further diagnostic interventions. When combined with a thorough patient history and physical examination, diagnostic procedures are essential in the evaluation of GI disorders. This chapter describes the most commonly used clinical tools to evaluate patients with GI tract–related diseases.

A variety of symptoms can arise from GI tract dysfunction, including heartburn, dyspepsia, abdominal pain, nausea, vomiting, diarrhea, constipation, and gastrointestinal bleeding. Signs and symptoms of malabsorption, hepatitis, and GI infection are also commonly seen. All clinicians must recognize warning symptoms that include weight loss, intractable vomiting, anemia, dysphagia, and bleeding; and a patient presenting with any of these symptoms should be immediately referred for further diagnostic interventions. The following sections describe methods that are commonly used to assess patients with GI complaints. For specific details concerning each GI disease state, please consult that particular chapter in this book.
A comprehensive patient history is the cornerstone in the evaluation of a patient with digestive complaints. A clear, detailed, chronologic account of the patient’s problems should be gathered. This account should include the onset of the problem, the setting in which it developed, factors that alleviate and aggravate the problem, and its manifestations. The symptom onset often provides important information that helps to formulate a differential diagnosis. For example, biliary colic or pain, such as that encountered with symptomatic gallstone disease, typically evolves over minutes and is present for hours, but pain caused by pancreatitis evolves over hours and lasts for days. The setting is always relevant as it provides clues to the possible origin of the disorder. For example, ingesting a meal often relieves the pain of duodenal ulcer, but worsens that of gastric ulcer. The healthcare professional should ask questions that address potential etiologic possibilities, including motility disorders, structural diseases, malignancies, infections, psychosocial factors, dietary factors, and travel-associated diseases.1,2 Questions concerning past medical and family history detailing illnesses, surgical interventions, injuries, foreign travel, living conditions, and habits are valuable (Table 38–1). A good cardiopulmonary history is also extremely relevant and should be performed during the overall history. A thorough medication use history is vital as many agents cause GI injury (Table 38–2).

Table 38–1 General Questions in a Gastrointestinal History

1. Tell me about the problem that you are experiencing. When did it start? What were you doing when the symptoms began?
2. Where is your pain located? Please point to the area where you feel pain. How rapidly did the pain come on? Is your pain constant or intermittent? What factors exacerbate or alleviate your pain? Does the pain awaken you at night?
3. Have you had these symptoms in the past?
4. What medications are you taking to alleviate the pain? How much do you take? Do these medications work?
5. What medications are you currently taking? Why are you taking them?
6. Have you recently had a change in dietary intake? If so, please describe. Can you draw any correlation between the foods that you eat and your gastrointestinal (GI) complaint?
7. Have you recently had a change in bowel habits? Have you experienced any diarrhea or constipation lately? Do you experience painful bowel movements?
8. Have you experienced any nausea or vomiting lately? If so, please describe conditions centered around this event.
9. Have you experienced any recent change in weight? Was this intentional? How many pounds have you gained or lost and over what time period did this occur? How has your appetite been?
10. Have you had these symptoms in the past? Have you passed any blood from your rectum or vomited blood? Have you noticed any dark, tarry stools?
11. Have you had any acid indigestion?
12. Do you have difficulty swallowing?
13. Has anyone in your family experienced similar GI complaints? If so, please describe. Does anyone in your family have a history of GI disorders, including cancer of the GI tract?
14. Describe your past medical history, including illnesses and surgeries.
15. Please describe any past injuries that you have experienced.
16. Have you recently traveled outside of the United States? If so, where? When? How long did you stay? What kind of living conditions did you experience? What foods and drinks did you ingest?

Many organ systems of the body interact and may provide important data needed for diagnosis, making it necessary to perform a thorough physical examination. A comprehensive evaluation of the patient should be performed with notable attention to physical appearances and vital signs as they may suggest clues. A careful examination of the abdomen is an essential part of the gastrointestinal workup and classically includes inspection, auscultation, percussion, and palpation in this order. Inspection of the abdomen may reveal scars, hernias, bulges, or peristalsis. Auscultation is mainly focused on analysis of bowel sounds and identification of bruits and should be performed prior to percussion and/or palpation. Percussion of the abdomen allows for detection of tympany, measurement of visceral organ size, and detection of ascites. Palpation may allow the clinician to identify tenderness, rigidity, masses, and hernias. Moving from the abdominal exam, the digital rectal examination is used to detect rectal masses and tenderness, and to assess muscle tone. Stool on the examiner’s glove obtained during rectal examination is often subjected to testing for detection of occult blood. Patients presenting with upper gastrointestinal symptoms need more careful questioning to distinguish symptoms of reflux disease versus peptic ulcer disease. Additionally, once cardiovascular disease is eliminated, patients with chest pain may have a gastrointestinal source to their symptoms and further diagnostic workup may be needed.

### LABORATORY AND MICROBIOLOGIC TESTS

Laboratory and microbiologic tests may be used to (a) assess organ function, (b) screen for certain GI disorders, and (c) evaluate the effectiveness of therapy. Laboratory testing should be viewed largely as supportive to an accurate history and physical examination. To achieve an accurate diagnosis and provide the best care, it is important to assess the patient’s fluid and electrolyte status, nutritional status, and abdominal organ function. A complete blood cell count should be completed early in the evaluation to provide information concerning infection, malignancy, bone marrow suppression, anemia, and blood loss. A serum chemistry panel provides clinicians with valuable information—involving several organ systems. For example, serum creatinine and blood urea nitrogen are often used as a measure of hydration status, as well as serving as indicators for renal function. Elevations in serum creatinine and blood urea nitrogen may be indicative of renal dysfunction or dehydration, and bleeding from the upper GI tract may lead to elevations in blood urea nitrogen. Albumin and prealbumin levels can be used to assess the patient’s nutritional and hydration status and provide information concerning hepatic and renal function. Specifically, low albumin may be indicative of malnutrition, hepatic dysfunction, nephrotic syndromes, or protein-losing enteropathies. Serum measurements of sodium, chloride, and potassium are useful to determine electrolyte abnormalities associated with diarrheal illnesses.

More specific laboratory blood tests are often useful in classifying pancreatobiliary disorders. Measurements of serum aspartate transaminase and alanine transaminase are elevated in most diseases of the liver, and serum alkaline phosphatase and bilirubin are often elevated in hepatobiliary disorders involving bile duct blockage. Prothrombin time and international normalized ratio are related to hepatocyte synthesis of vitamin K–dependent clotting factors and serve as indirect measurements of hepatic function. When evaluating patients with suspected pancreatitis, serum and urine measurements of amylase and lipase are important, because these will be elevated in many patients with acute pancreatitis (see Chapter 46).

Microbiologic and related studies are useful in evaluating patients with unexplained diarrhea, abdominal pain, and suspected GI infections. Stool may be examined to detect the presence of bacteria, parasites, or toxins. Pathogens most often responsible for infectious diarrhea and enteritis include bacteria such as Shigella, Salmonella, Escherichia coli, Yersinia, and Clostridium difficile. Viruses such as cytomegalovirus, especially in patients with acquired immune deficiency syndrome (AIDS), and parasites such as Entamoeba histolytica and Giardia lamblia are occasionally seen. Patients presenting with watery diarrhea following antibiotic exposure within the previous 1 to 3 months should have their stool checked for C difficile toxins A and B. An additional organism Helicobacter pylori is a significant factor associated with peptic ulcer disease and MALT lymphomas; identification of this organism is critical in patients experiencing upper gastrointestinal symptoms and is often tested for during upper endoscopy (see Chapter 40).

### DIAGNOSIS

The patient’s history, physical examination, and routine laboratory tests are valuable in establishing a diagnosis, but frequently more specific studies are required to confirm a clinical suspicion. The most appropriate diagnostic test depends on the anatomic region involved, the suspected abnormality, reliability of the test (e.g., sensitivity vs specificity), the patient’s overall condition, and clinical manifestations of the patient. The next sections outline the most frequently used diagnostic studies and procedures and their roles in evaluating the GI tract.

### RADIOLOGY

Radiologic procedures rely on the differential absorption of radiation of adjacent tissues to highlight anatomy and pathology. It is useful to divide radiologic testing into noncomputer- and computer-assisted procedures. Noncomputer-assisted radiologic procedures important in evaluating the GI tract include plain radiography, upper GI series with small bowel follow-through, lower GI series, and enteroclysis.

#### Plain Radiography of the GI System

Radiographic evaluation of the GI tract often starts with plain films of the abdomen, which are noncontrast radiographs. Specific abdominal structures that may be identified include the kidneys, ureters, and bladder. In addition, the esophagus, stomach, small and large intestine, and stones may be seen. Stones located within the gallbladder body and within the kidney are also sometimes seen on plain abdominal films. Plain films are often used to evaluate abdominal pain. Clinicians frequently employ plain radiographic fluoroscopy to guide and position other instruments that are used to evaluate and treat GI disorders; an example is the manipulation of dilation devices to treat esophageal strictures. Bowel obstruction and perforation are also sometimes seen using plain radiographic techniques, however the widespread availability of computed tomography (CT) scanning is gradually replacing these techniques.

#### Contrast Agents

Barium sulfate and/or gastrograffin are the contrast agents of choice for studying the esophagus, stomach, and intestine. Barium sulfate is a metallic material detected by radiography after swallowing the liquid agent; it is termed the barium swallow. Barium sulfate is not generally absorbed, and constipation is the most frequent adverse effect reported with its use. Barium sulfate and/or gastrograffin can reveal mucosal defects and lumen size, and is helpful in diagnosing hiatal hernias, strictures along the GI tract, polyps, tumors, and in some cases ulcers. Upper endoscopy is largely replacing the contrast studies in the diagnosis of upper
GI tract disorders, but in certain instances can be a valuable tool in establishing a diagnosis prior to endoscopic evaluation. The barium esophagram should not serve as a primary diagnostic tool for patients with heartburn.

**Upper GI Series**

The upper GI series refers to the radiographic visualization of the esophagus, stomach, and small intestine. Patient preparation for an upper GI series usually consists of instructing patients to refrain from eating or drinking 8 to 12 hours prior to testing, which allows the upper GI tract to empty. A contrast agent such as barium sulfate or gastrograffin is administered to the patient at the beginning of the study. The observed swallowing of the contrast agent permits visualization and monitoring of esophageal structural and motor functions. As the contrast medium flows into the stomach and small intestine, several regional radiographic films are taken to inspect these areas. This tracking of contrast agents through the small intestine is referred to as the small bowel follow-through. The upper GI series with small bowel follow-through commonly uncovers gastric cancer, peptic ulcer disease, esophagitis, gastric outlet obstruction, and can be suggestive of Crohn’s disease (Fig. 38–1). In general, the barium swallow is plagued by low sensitivity and specificity for many GI disorders and as mentioned is being replaced by upper endoscopic techniques.

**Lower GI Series**

The lower GI series is used to examine the colon and rectum and is particularly useful if a colonic obstruction is suspected. Patients complaining of lower abdominal pain, constipation, or diarrhea are often referred for a lower GI series, also called a barium enema. The colon is prepared for the procedure by instructing the patient to refrain from eating or drinking 8 to 12 hours before the procedure, and by administering bowel-cleansing agents such as bisacodyl, magnesium citrate, magnesium hydroxide, or polyethylene glycol electrolyte (PEG) solution. During a lower GI series, a barium sulfate enema is given to contrast the terminal large intestine and rectum. The lower GI series is sometimes useful to detect and evaluate enterocolitis, obstructions, volvulus, and mucosal and structural lesions.

**Small Bowel Enteroclysis**

Enteroclysis, or small bowel enema, refers to the technique of direct small bowel introduction of a contrast agent through a tube inserted through the patient’s mouth or nose directly into the small intestine. Sequential radiographic films are taken of the small bowel as the contrast agent flows distally (Fig. 38–2). Because enteroclysis provides detailed imaging, it is an accurate method for evaluating the small bowel and for detecting small mucosal lesions that may be overlooked on the traditional small bowel follow-through. Methylcellulose is used to enhance the detail of the small intestine in enteroclysis, thereby improving visualization. Patient preparation for this procedure involves instructing patients to refrain from eating or drinking 8 to 12 hours before testing and administering bowel-cleansing agents. The enteroclysis technique is a useful study for evaluation of the upper GI tract, but unfortunately it is not widely performed due to operator inexperience and is gradually being replaced by improved radiologic techniques such as CT or magnetic resonance imaging (MRI) enterography or more recently by small intestinal endoscopy known as single and double balloon enteroscopy.

**IMAGING STUDIES**

The second category of radiologic evaluation of the GI tract involves computer-assisted techniques, which allow a cross-sectional radiographic image of the body to be performed. Transabdominal ultrasonography, computed tomography, radionuclide scanning, and magnetic resonance imaging are frequently used imaging procedures for evaluating digestive disorders.

**Ultrasonography**

Ultrasonography provides images of deeper structures such as the gallbladder, liver, and kidneys and can also be very useful in helping to define vascular abnormalities in the intra-abdominal
Evaluation of the Gastrointestinal Tract

CHAPTER 38

Radionuclide Imaging

Radionuclide imaging involves intravenous injections of a radiopharmaceutical imaging agent and the use of a computerized detection camera to gather images. A secretory agent is sometimes given in addition to the radiopharmaceutical agent to improve sensitivity. Although the choice of a radiopharmaceutical agent depends on the specific organ or function being studied, the most commonly used agent is technetium (99m Tc) tagged to a carrier molecule. Radionuclide imaging is sometimes useful to visualize the liver and spleen (liver-spleen scan), bile ducts, gallbladder (HIDA [hepatoiminodiacetic acid] scan), and gut (tagged red blood cell). Cysts, abscesses, tumors, and obstructions are detected and displayed as areas of differential uptake of radioactivity. Radionuclide bleeding scans may detect hemorrhages and may assist in localization to help with therapeutic intervention. Contrast media nephrotoxicity in patients with preexisting renal impairment remains a clinically significant problem. Pretest treatment in high-risk patients with pharmacologic agents has demonstrated mixed results.

Magnetic Resonance Imaging

Magnetic resonance imaging and magnetic resonance cholangiopancreatography (MRCP) places the patient in close proximity to a high-strength magnetic field through which pulses of radiofrequency radiation are projected, thereby exciting the nuclei of hydrogen, phosphorus, oxygen, and other elements. The radiofrequency signals are manipulated and recorded by a computer, and a two-dimensional image representing a section of the patient is produced. MRI has greater sensitivity for identifying liver tumors than do ultrasonography, CT, and radionuclide imaging. Significant advances in MRI technology and imaging capabilities often make this a preferred diagnostic test, particularly in the evaluation of pancreaticobiliary disorders.

Arteriography

Arteriography of the gut depicts the configuration of visceral blood vessels after intravenous administration of a contrast medium. Arteriography may be employed for vascular anomalies such as an aneurismal dilation and in the evaluation of obscure bleeding.
lesions. Therapeutic applications, including embolization of bleeding vessels, fistulas, and inoperable tumors.

ENDOSCOPY

Refinement in optical engineering and fiber optics led to the development of the endoscope, which has revolutionized the management of GI disorders. Most endoscopic equipment today uses a computer chip device to provide high definition, detailed images of the particular lumen being examined. An endoscope is an illuminated white light and non-white light optical instrument designed to inspect the interior of the GI tract. Endoscopes enable the practitioner to inspect intraluminal mucosal lesions and to obtain biopsies and washings for cytology studies. Standard upper GI tract endoscopy (i.e., esophagogastroduodenoscopy [EGD]) is capable of inspecting the esophagus, stomach, and proximal small bowel. Lower GI tract endoscopic evaluation of the rectum and colon may be accomplished by colonoscopy or flexible-sigmoidoscopy. Standard upper and lower endoscopy can also be used to perform many therapeutic procedures and in addition many newer diagnostic and therapeutic endoscopic devices are now available.

Preparation for endoscopic examinations includes instructing patients to refrain from eating or drinking for at least 8 to 12 hours prior to the endoscopic procedure. Bowel cleansing is necessary for colonoscopy and sigmoidoscopy using a variety of PEG-based solutions. Topical pharyngeal anesthetics, such as viscous lidocaine or benzocaine, usually improve patient acceptance of the upper endoscopic tube. Intravenous sedating agents, such as the benzodiazepines, lorazepam, midazolam, and, more recently, propofol, are among the most common agents used to induce differing levels of sedation, most commonly “conscious sedation” prior to the endoscopy. These sedating agents tend to improve patient acceptance and ease of the procedure. The agents should not be used without appropriate monitoring and the availability of flumazenil, a benzodiazepine antagonist. Serious adverse events have occurred with these agents when used for conscious sedation. In addition, antimuscarinic agents such as atropine sulfate are occasionally used for their cardiovascular effects, such as increasing a patient’s heart rate, or for their antispasmodic effects, such as reducing duodenal and colonic motility. Because of its effectiveness at reducing bowel motility, glucagon may be used. Endoscopy should be pursued with caution in patients with severe respiratory or cardiac failure, and endoscopy is contraindicated for patients with suspected perforated viscera. The most commonly used endoscopic studies are upper endoscopy (EGD), colonoscopy, flexible sigmoidoscopy, and endoscopic retrograde cholangiopancreatography (ERCP). Newer endoscopic techniques include capsule endoscopy, endoscopic ultrasound (EUS), and single or double balloon enteroscopy. These techniques are outlined in detail below.

Esophagogastroduodenoscopy is used to examine the esophagus, stomach, and duodenum. Patient preparation for EGD includes fasting for at least 6 to 8 hours prior to the procedure and the administration of sedatives and topical anesthetics. Common indications include evaluation of suspected upper GI bleeding, obstructions, upper abdominal pain, and persistent vomiting. Evaluation of radiographic abnormalities is also a frequent procedural indication. EGD can be used therapeutically in upper gastrointestinal bleeding for ligation procedures involving esophageal varices, sclerosing or vasoconstrictive agent administration at the site of the bleed in peptic ulcer induced bleeding, or via the use of a thermal device such as a gold probe or heater probe on a bleeding vessel. In addition to its therapeutic potential, EGD commonly uncovers peptic ulcer disease and is the method of choice to diagnose Barrett’s esophagus, a premalignant condition of the esophagus and other esophageal ulcer erosive disorders (Fig. 38–5). Once viewed as the method of choice to diagnosis gastroesophageal reflux disease, upper endoscopy, although commonly used, is often times not performed before a trial of a proton pump inhibitor has been undertaken. The favorable side-effect profile of proton pump inhibitors in addition to their superior healing ability make these agents extremely power-
ful and widely prescribed by primary care physicians for heartburn and other symptoms attributed to gastroesophageal reflux disease. Primary care physicians usually refer patients for EGD only when they fail to respond to a course of proton pump inhibitor therapy, and by the time an endoscopy is performed the examination is likely to reveal normal-appearing mucosa. Even in patients undergoing upper endoscopy in the evaluation of reflux type symptomatology in the absence of proton pump inhibitor therapy, endoscopy will be normal in up to 50% of patients. 9

Colonoscopy
Colonoscopy permits direct examination of the large intestine and rectum. To prepare for colonoscopy, the patient should fast for at least 8 to 12 hours prior to the examination, and bowel cleansing should be completed. Bowel preparations have traditionally involved a PEG-based or phosphate-based solution. However, because of concerns regarding phosphate-induced nephropathy, there has been a return to standard PEG-based solutions. A benzodiazepine and a short-acting narcotic agent are given to produce conscious sedation and in patients refractory or intolerant to conscious sedation agents, propofol is often administered to provide a deeper level of sedation. As with upper GI endoscopy, indications for lower GI endoscopy can be either diagnostic or therapeutic in nature. Common indications include evaluation and detection of abnormalities visualized by radiography, as well as diagnosis and therapy of GI hemorrhage, and importantly, screening patients for colorectal carcinoma. Additionally colonoscopy remains an invaluable procedure in the diagnosis, staging, and therapy of patients with inflammatory bowel disease (e.g., ulcerative colitis and Crohn’s disease). 9

Sigmoidoscopy
Flexible sigmoidoscopy is used to evaluate the sigmoid colon via the anorectum (Fig. 38-6). Flexible sigmoidoscopy has virtually replaced rigid sigmoidoscopy because of increased patient comfort and superior performance. The major indication for this examination is to evaluate symptoms related to the distal colon or rectum, such as hematochezia, painful defecation, and unexplained diarrhea. Flexible sigmoidoscopy is gradually being replaced by full colonoscopy in the evaluation and screening of patients for colorectal carcinoma. Patient preparation involves instructing patients to abstain from eating or drinking for at least 8 hours prior to the procedure and the administering of bowel-cleansing agents. Anoscopy is especially useful in evaluating the anus. The major indications for anoscopy include symptoms related to the anus and rectum, such as bleeding, protruding anorectal lesions, pain with defecation in particular, and severe itching. Patients undergoing sigmoidoscopy or anoscopy generally do not require sedation.

Endoscopic Retrograde Cholangiopancreatography
Endoscopic retrograde cholangiopancreatography is an important procedure that is used to evaluate and treat diseases of the pancreaticobiliary tree. Common indications include common bile duct stone diagnosis and management, bile and pancreatic duct stricture management, and in the diagnosis and therapy of patients with biliary tract and/or pancreatic malignancies. Contrast injection following wire-guided bile or pancreatic duct cannulation reveals abnormalities such as obstruction due to malignancy or fluid collections, calculi, and strictures can be examined. ERCP also allows for the use of therapeutic techniques such as biliary or pancreatic sphincterotomy, removal of ductal stones from the common bile duct or main pancreatic duct, and in the stenting of biliary or pancreatic strictures. ERCP is also a useful method for tissue acquisition in the pancreaticobiliary tract using a variety of brush and biopsy devices. Recent advances in ERCP include the addition of direct bile duct or pancreatic duct visualization, a procedure which has greatly aided in the diagnosis and therapy of pancreaticobiliary disorders. Preparation for ERCP consists of conscious sedation and glucagon to relax gut motility and often requires the use of an anesthesiologist due to the complex and long procedural times associated with ERCP (Fig. 38-7). 7,9

Endoscopic Ultrasound
Endoscopic ultrasound is a newer, exciting endoscopic technology which represents a marriage between upper endoscopy and standard ultrasound techniques. A high frequency ultrasound probe is attached to the working end of a diagnostic (radial array) or therapeutic (linear array) oblique viewing echoendoscope. Endoscopic ultrasound is commonly used to stage and diagnose upper GI tract malignancies such as those involving the esophagus, stomach, and pancreas. Upper GI tract locoregional tumor staging and tissue acquisition is highly sensitive and specific and provides a less invasive manner of tissue acquisition in many cases. Expanded uses of EUS include diagnosis and management of pancreatic fluid collections including pancreatic cystic neoplasms (non-pseudocystic), celiac plexus block vs neurolysis in pancreatic malignant and chronic pancreatitis patients, and in some centers in the direct instillation of antitumor agents into
pancreatic malignancies. Lower GI tract EUS is also commonly performed most often in the diagnosis and locoregional staging of anorectal carcinoma and in evaluation of the anal sphincters. EUS is an invaluable tool in the management of GI tract disorders but does remain centered largely in academic, tertiary care referral institutions.

**Enteroscopy**

Enteroscopy, or direct visualization of the small intestine, has traditionally been limited to examination of the proximal most portions of the duodenum/jejunum because of excessive endoscope looping and discomfort to the patient during the examination. To overcome these difficulties two newer techniques, single and double balloon enteroscopy, have been developed. These particular enteroscopes involve sequential inflation and deflation of balloon attachment devices in order to sequentially “walk” the enteroscope down the small or large intestine. A combination of inflation, deflation, and endoscope reduction via torque and withdrawal allow for a pleating of the mucosal surface being examined. Complete traversal of the small intestine is routinely achieved via the oral route and significant traversal of the colon and distal small intestine is now possible from the rectal route. Common indications for these procedures include the evaluation of obscure GI bleeding, the diagnosis and evaluation of possible inflammatory bowel disease, and in the evaluation of radiologically discovered lesions such as mass or bowel wall thickening.

**Capsule Endoscopy**

Capsule endoscopy allows the visualization of the esophagus, stomach, and small intestine. This device consists of a vitamin pill-sized video camera that is swallowed and acts as an endoscope (Fig. 38–8). As the video capsule travels naturally through the digestive tract, images are transmitted to a recording device placed on the patient’s hip. Patients return the recording device to the practitioner so that the images can be downloaded to a computer and evaluated. Eventually, the camera is naturally excreted and not retrieved. Capsule endoscopy represents a noninvasive means to evaluate the upper and lower GI tracts but unfortunately lacks therapeutic capability. Capsule endoscopy is often used in the evaluation of obscure GI bleeding and in the evaluation of suspected inflammatory bowel disease and is often times used in conjunction with single or double balloon enteroscopy.

**MISCELLANEOUS TESTS**

**Esophageal Manometry**

Esophageal manometry is used to evaluate diseases of the esophagus by assessing esophageal motor functions. Common indications for this procedure include dysphagia and obscure chest pain. A special catheter equipped with pressure transducers is placed into the esophagus to measure esophageal pressures and peristalsis. Provocative testing with pharmacologic agents such as edrophonium chloride, a cholinergic muscle stimulant, may be used to precipitate esophageal pain during this procedure. Typical indications for esophageal manometry include evaluating suspected esophageal dysmotility, nonobstructive dysphagia, obscure chest pain, intestinal pseudo-obstruction, achalasia, and aiding in the positioning instruments such as pH probes. Esophageal manometry almost always is performed following endoscopic evaluation of the upper GI tract and can be a valuable tool in diagnosing many nonspecific disorders of the upper GI tract.

**Ambulatory Esophageal pH Monitoring**

Esophageal pH monitoring is considered by many clinicians as the gold standard in the evaluation of patients who complain
Wireless pH monitoring systems have gradually replaced the older methods that required a wire probe placement. A capsule is attached to the distal esophagus by a delivery system. The capsule then transmits measured pH data to a receiver by radiotelemetry technique. Wireless systems offer the advantage of better patient acceptance and extended monitoring of up to 96 hours versus 24 hours of the wire method. There are limitations to ambulatory pH monitoring in patients receiving proton pump inhibitor therapy or in the detection of nonacidic or weakly acidic reflux. 

Multichannel intraluminal impedance monitoring is an emerging technique to study acid and nonacid reflux. The method combines pH measurements with manometry that enables the measurement of and distinction between swallowing and reflux. In patients whose symptoms have not responded to empiric proton pump inhibitor therapy in GERD, the test can separate those in whom symptoms are associated with acid reflux from those in whom symptoms are associated with nonacid reflux. Outcomes studies are required to further evaluate the usefulness of this diagnostic method; however, accumulating data are extremely promising.

The Bernstein test, an older procedure that is used to measure gastric fluid pH, has largely been replaced by ambulatory pH monitoring. The procedure requires inserting a nasogastric tube and administrating alternating dripped solutions of normal saline and 0.1 N hydrochloric acid (HCl) into the esophagus via the nasogastric tube. If patient symptoms are reproduced by the acid perfusion and not the saline, the study is considered abnormal and indicative of acid hypersensitivity.

**Laparoscopy**

Laparoscopy uses a tube-like device with an elaborate optical system that permits distinct visualization of the peritoneal cavity. General anesthesia is often required and a surgical incision is made in the abdomen to allow the passage of the laparoscope. The exterior of the liver, gallbladder, spleen, peritoneum, diaphragm, and pelvic organs may be examined during the laparoscopic examination. Similar to the other endoscopic techniques mentioned, biopsies and therapeutic interventions may be performed during the laparoscopy. Laparoscopy, it is important to remember, is extremely invasive. Reasons for doing laparoscopy include evaluating patients with abdominal masses, chronic abdominal pain of unclear etiology, abnormalities indicated on liver-spleen scan, such as acute or chronic cholecystitis, and to aid in the diagnosis and management of intra-abdominal malignancy.

**CONCLUSIONS**

Evaluation of the GI tract begins with a careful history and comprehensive physical examination. It then proceeds in a deliberate and thoughtful manner to establish the correct diagnosis and appropriate management of a given GI tract problem. Laboratory and microbiologic testing in addition to appropriate radiologic evaluation are often the initial steps in the evaluation of a patient with a particular GI tract complaint. GI tract endoscopy using a wide range of endoscopic devices with both diagnostic and therapeutic potential has entered the GI tract mainstream in recent years. Despite the wide array of testing and procedures available clinicians need to continue to perform a thorough history and physical examination and should be keenly aware of warning signs and symptoms that require immediate referral for further diagnostic studies and possible therapeutic intervention.

**ABBREVIATIONS**

CAT: computed axial tomography
CT: computed tomography
EGD: esophagogastroduodenoscopy
ERCP: endoscopic retrograde cholangiopancreatography
EUS: endoscopic ultrasound
MRCP: magnetic resonance cholangiopancreatography
MRI: magnetic resonance imaging
PEG: polyethylene glycol electrolyte solution

**REFERENCES**

Gastroesophageal Reflux Disease

DIANNE B. WILLIAMS AND ROBERT R. SCHADE

**KEY CONCEPTS**

1. Esophageal gastroesophageal reflux disease (GERD) syndromes can be described as symptom based or esophageal tissue injury based.

2. Endoscopy is used to evaluate mucosal damage from GERD and to assess for the presence of Barrett esophagus or other complications; ambulatory pH monitoring (with or without impedance monitoring) is useful for confirming GERD for patients with persistent symptoms without evidence of mucosal damage or for patients with atypical symptoms; manometry is useful for patients who are candidates for antireflux surgery and for ensuring proper placement of pH probes.

3. The goals of GERD treatment are to alleviate symptoms, decrease the frequency of recurrent disease, promote healing of mucosal injury, and prevent complications.

4. GERD treatment is determined by disease severity and includes lifestyle changes and patient-directed therapy, pharmacologic treatment, and antireflux surgery.

5. Patients with typical esophageal GERD syndromes should be treated with lifestyle modifications as appropriate and a trial of empiric acid-suppression therapy. Those who do not respond to empiric therapy or who present with alarm symptoms should undergo endoscopy.

6. Surgical intervention is a viable alternative treatment for select patients when long-term pharmacologic management is undesirable.

7. Acid suppression is the mainstay of GERD treatment. Proton pump inhibitors provide the greatest symptom relief and the highest healing rates, especially for patients with erosive disease or moderate to severe symptoms.

8. Many patients with GERD will relapse if treatment medication is withdrawn; so long-term maintenance treatment may be required. A proton pump inhibitor is the drug of choice for maintenance of patients with moderate to severe GERD.

Gastroesophageal reflux disease (GERD) is a common medical disorder. A consensus definition of GERD states it is “a condition that occurs when the refluxed stomach contents lead to troublesome symptoms and/or complications.” The key is that these troublesome symptoms adversely affect the well-being of the patient. Episodic heartburn that is not frequent enough or painful enough to be considered bothersome by the patient is not included in this definition of GERD.

Esophageal GERD syndromes are classified as either symptom-based or tissue injury based depending on how the patient presents. Symptom-based esophageal GERD syndromes may exist with or without esophageal injury and most commonly present as heartburn, regurgitation or dysphagia. Less commonly, odynophagia (painful swallowing) or hypersalivation may occur. Tissue injury–based syndromes may exist with or without symptoms. The spectrum of injury includes esophagitis (inflammation of the lining of the esophagus), Barrett esophagus (when tissue lining the esophagus is replaced by tissue similar to the lining of the intestine), strictures, and esophageal adenocarcinoma. Esophagitis occurs when the esophagus is repeatedly exposed to refluxed gastric contents for prolonged periods of time. This can progress to erosion of the squamous epithelium of the esophagus (erosive esophagitis). Complications of long-term reflux may include the development of strictures, Barrett esophagus, or possibly adenocarcinoma of the esophagus.

Gastroesophageal reflux symptoms associated with disease processes in organs other than the esophagus are referred to as extraesophageal reflux syndromes. Patients with extraesophageal reflux syndromes may present with reflux chest pain syndrome, laryngitis, or asthma. An association between these syndromes and GERD should only be considered when they occur along with esophageal GERD syndrome because these extraesophageal symptoms are non-specific and have many other causes.

Inflammation of the esophagitis (reflux esophagitis) can sometimes progress to erosions of the squamous epithelium of the esophagus; this is known as erosive esophagitis. Many patients suffering from mild GERD do not go on to develop erosive esophagitis and are often managed with lifestyle changes, antacids, and nonprescription histamine-2 (H2) receptor antagonists or nonprescription proton pump inhibitors. Those with more severe symptoms (with or without tissue injury) predictably follow a course of relapsing disease, requiring more intensive treatment with acid-suppression therapy followed by long-term maintenance therapy. Antireflux surgery offers an alternative for select patients in whom prolonged medical management is undesirable.

EPIDEMIOLOGY

Gastroesophageal reflux disease occurs in people of all ages but is most common in those older than age 40 years. Although mortality associated with GERD is rare, GERD symptoms may have a significant impact on quality of life. The true prevalence and incidence of GERD is difficult to assess because many patients do not seek medical treatment, symptoms do not always correlate well with the severity of the disease, and there is no standardized definition or universal gold standard method for diagnosing the disease. However, 10% to 20% of adults in Western countries suffer from GERD symptoms on a weekly basis.3

The prevalence of GERD varies depending on the geographic region but appears highest in Western countries.5 Except during pregnancy, there does not appear to be a major difference in incidence between men and women. Although gender does not generally play a major role in the development of GERD, it is an important factor in the development of Barrett esophagus. Barrett esophagus is most prevalent in white adult males in Western countries and may increase the risk for adenocarcinoma of the esophagus especially in white males. Alarming, adenocarcinoma of the esophagus has increased two- to sixfold over the past 2 decades.2

The relationship of adenocarcinoma to Barrett esophagus, or even just long-standing GERD, which may be an independent risk factor for esophageal adenocarcinoma, is not clear.

Other risk factors and comorbidities that may contribute to the development or worsening of GERD symptoms include family history, obesity, smoking, alcohol consumption, certain medications and foods, respiratory diseases, and reflux chest pain syndrome.

PATHOPHYSIOLOGY

The key factor in the development of GERD is the abnormal reflux of gastric contents from the stomach into the esophagus.3 In some cases, gastroesophageal reflux is associated with defective lower esophageal sphincter (LES) pressure or function. Patients may have decreased gastroesophageal sphincter pressures related to (a) spontaneous transient LES relaxations, (b) transient increases in intraabdominal pressure, or (c) an atonic LES, all of which may lead to the development of gastroesophageal reflux. Problems with other normal mucosal defense mechanisms, such as abnormal esophageal anatomy, improper esophageal clearance of gastric fluids, reduced mucosal resistance to acid, delayed or ineffective gastric emptying, inadequate production of epidermal growth factor, and reduced salivary buffering of acid, may also contribute to the development of GERD. Substances that may promote esophageal damage upon reflux into the esophagus include gastric acid, pepsin, bile acids, and pancreatic enzymes. Thus the composition and volume of the refluxate, as well as duration of exposure, are important aggressive factors in determining the consequences of gastroesophageal reflux. Rational therapeutic regimens in the treatment of gastroesophageal reflux are designed to maximize normal mucosal defense mechanisms and attenuate the aggressive factors.

LOWER ESOPHAGEAL SPHINCTER PRESSURE

The lower esophageal sphincter is a manometrically defined zone at the distal esophagus with an elevated basal resting pressure. The sphincter is normally in a tonic, contracted state, preventing the reflux of gastric material from the stomach but relaxes on swallowing to permit the free passage of food into the stomach. Mechanisms by which defective LES pressure may cause gastroesophageal reflux are threefold. First, and probably most importantly, reflux may occur following spontaneous transient LES relaxations that are not associated with swallowing. Although the exact mechanism is unknown, esophageal distension, vomiting, belching, and retching cause relaxation of the LES. While not thought to contribute significantly to erosive esophagitis, these transient relaxations, which are normal postprandially, may play an important role in symptom-based esophageal reflux syndromes. Transient decreases in sphincter pressure are responsible for more than half of the reflux episodes in patients with GERD. The propensity to develop gastroesophageal reflux secondary to transient decreases in LES pressure is probably dependent on numerous factors, including the degree of sphincter relaxation, efficacy of esophageal clearance, patient position (more common in recumbent position), gastric volume, and intragastric pressure. Second, reflux may occur following transient increases in intraabdominal pressure (stress reflux). An increase in intraabdominal pressure such as that occurring during straining, bending over, coughing, eating, or a Valsalva maneuver may overcome a weak LES, and thus may lead to reflux. Third, the LES may be atonic, thus permitting free reflux as seen in patients with scleroderma. Although transient relaxations are more likely to occur when there is normal LES pressure, the latter two mechanisms are more likely to occur when the LES pressure is decreased by such factors as fatty foods, gastric distension, smoking, or certain medications (Table 39–1).5 Various foods aggravate esophageal reflux by decreasing LES pressure or by precipitating symptomatic reflux by direct mucosal irritation (e.g., spicy foods, orange juice, tomato juice, and coffee). Pregnancy is a condition in which reflux is common. There are many postulated reasons for the increased incidence of heartburn during pregnancy, including hormonal effects on esophageal muscle, LES tone, and physical factors (increased intraabdominal pressure) resulting from an enlarging uterus. A decrease in LES pressure resulting from any of the previously mentioned causes is not always associated with gastroesophageal reflux. Likewise, individuals who experience decreases in sphincter pressures and subsequently reflux, do not always develop GERD. The other natural defense mechanisms (anatomic factors, esophageal clearance,

mucosal resistance, and other gastric factors) must be evoked to explain this phenomenon.

ANATOMIC FACTORS

Disruption of the normal anatomic barriers by a hiatal hernia (when a portion of the stomach protrudes through the diaphragm into the chest) was once thought to be a primary etiology of gastroesophageal reflux and esophagitis. Now it appears that a more important factor related to the presence or absence of symptoms in patients with hiatal hernia is the LES pressure. Patients with hypotensive LES pressures and large hiatal hernias are more likely to experience gastroesophageal reflux following abrupt increases in intraabdominal pressure compared with patients with a hypotensive LES and no hiatal hernia. Although anatomic factors are still considered significant by some, the diagnosis of hiatal hernia is currently considered a separate entity with which gastroesophageal reflux may simultaneously occur.

ESOPHAGEAL CLEARANCE

In many patients with GERD, the problem is not that they produce too much acid but that the acid produced spends too much time in contact with the esophageal mucosa. This is not surprising, because the symptoms and/or severity of damage produced by gastroesophageal reflux are partially dependent on the duration of contact between the gastric contents and the esophageal mucosa. This contact time is, in turn, dependent on the rate at which the esophagus clears the noxious material, as well as the frequency of reflux. The esophagus is cleared by primary peristalsis in response to swallowing, or by secondary peristalsis in response to esophageal distension and gravitational effects. Swallowing contributes to esophageal clearance by increasing salivary flow. Saliva contains bicarbonate that buffers the residual gastric material on the surface of the esophagus. The production of saliva decreases with increasing age, making it more difficult to maintain a neutral intraesophageal pH. Therefore, esophageal damage caused by reflux occurs more often in the elderly and similarly for patients with Sjögren syndrome or xerostomia. Swallowing is also decreased during sleep, making nocturnal GERD a problem in many patients.

MUCOSAL RESISTANCE

Within the esophageal mucosa and submucosa there are mucus-secreting glands that may contribute to the protection of the esophagus. Bicarbonate moving from the blood to the lumen can neutralize acidic refluxate in the esophagus. When the mucosa is repeatedly exposed to the refluxate in GERD, or if there is a defect in the normal mucosal defenses, hydrogen ions diffuse into the mucosa, leading to the cellular acidification and necrosis that ultimately cause esophagitis. In theory, mucosal resistance may be related not only to esophageal mucus but also to tight epithelial junctions, epithelial cell turnover, nitrogen balance, mucosal blood flow, tissue prostaglandins, and the acid–base status of the tissue. Saliva is also rich in epidermal growth factor, stimulating cell renewal.

GASTRIC EMPTYING

Delayed gastric emptying can contribute to gastroesophageal reflux. An increase in gastric volume may increase both the frequency of reflux and the amount of gastric fluid available to be refluxed. Gastric volume is related to the volume of material ingested, rate of gastric secretion, rate of gastric emptying, and amount and frequency of duodenal reflux into the stomach. Factors that increase gastric volume and/or decrease gastric emptying, such as smoking and high-fat meals, are often associated with gastroesophageal reflux. This partially explains the prevalence of postprandial gastroesophageal reflux. Fatty foods may increase postprandial gastroesophageal reflux by increasing gastric volume, delaying the gastric emptying rate, and decreasing the LES pressure. Patients with gastroesophageal reflux, particularly infants, may have a defect in gastric antral motility. The delay in emptying may promote regurgitation of feedings, which might, in turn, contribute to two common complications of GERD in infants (e.g., failure to thrive and pulmonary aspiration).

COMPOSITION OF REFLUXATE

The composition, pH, and volume of the refluxate are important aggressive factors in determining the consequences of gastroesophageal reflux. In animals, acid has two primary effects when it refluxes into the esophagus. First, if the pH of the refluxate is less than 2, esophagitis may develop secondary to protein denaturation. In addition, pepsinogen is activated to pepsin at this pH and may also cause esophagitis. Duodenogastric reflux esophagitis, or “alkaline esophagitis,” refers to esophagitis induced by the reflux of biliary and pancreatic fluid. The term alkaline esophagitis may be a misnomer in that the refluxate may be either weakly alkaline or acidic in nature. An increase in gastric bile concentrations may be caused by duodenogastric reflux as a result of a generalized motility disorder, slower clearance of the refluxate, or after surgery. Although bile acids have both a direct irritant effect on the esophageal mucosa and an indirect effect of increasing hydrogen ion permeability of the mucosa, symptoms are more often related to acid reflux than to bile reflux. Specifically, the percentage of time that the esophageal pH is <4 is greater for patients with severe disease as compared with those with mild disease. Esophageal pH monitoring in conjunction with 24-hour bile monitoring has shown a higher incidence of Barrett esophagus for patients who have both acid and alkaline reflux. More study is needed to substantiate this finding. Nevertheless, the combination of acid, pepsin, and/or bile is a potent refluxate in producing esophageal damage.

COMPLICATIONS

Several complications may occur with gastroesophageal reflux, including esophagitis, esophageal strictures, Barrett esophagus, and esophageal adenocarcinoma. Strictures are common in the distal esophagus and are generally 1 to 2 cm in length. The use of non-steroidal antiinflammatory drugs or aspirin is an additional risk factor that may contribute to the development or worsening of GERD complications. Although GERD may lead to esophageal bleeding, the blood loss is usually chronic and low grade in nature, but anemia may occur. In some patients, the reparative process leads to the replacement of the squamous epithelial lining of the esophagus by specialized columnar-type epithelium (Barrett esophagus), which increases the incidence of esophageal strictures by as much as 30%. Additionally, the risk of esophageal adenocarcinoma may be higher for patients with Barrett esophagus as compared with the general population.

The pathophysiology of gastroesophageal reflux is a complex cyclic process. It is difficult, if not impossible, to determine which occurs first: gastroesophageal reflux leading to defective peristalsis with delayed clearing or an incompetent LES pressure leading to gastroesophageal reflux. Understanding the factors associated with the development of GERD provides insight into the treatment modalities currently used to manage patients suffering from this disease.
**CLINICAL PRESENTATION**

1. Gastroesophageal reflux disease (GERD) syndromes can be described as symptom-based or esophageal tissue injury-based. Patients may also present with more complicated “alarm” symptoms which necessitates further diagnostic evaluation to differentiate other diseases as the cause. The spectrum of esophageal injury-based GERD syndromes includes esophagitis, strictures, Barrett esophagus, and adenocarcinoma. The severity of the symptoms of gastroesophageal reflux does not always correlate with the degree of esophageal tissue injury, but it does correlate with the duration of reflux. Patients with symptom-based esophageal syndromes may have symptoms as severe as those with esophageal tissue injury. Patients may also present with extraeosophageal syndromes that include atypical symptoms such as reflux chest pain syndrome, laryngitis, or asthma. It is important to distinguish GERD symptoms from those of other diseases, especially when chest pain or pulmonary symptoms are present. Interestingly, close to half of patients presenting with chest pain who have a normal electrocardiogram have GERD and approximately half of patients with asthma have GERD.

The most useful tool in the diagnosis of gastroesophageal reflux is the clinical history, including presenting symptoms and associated risk factors. Patients presenting with typical symptoms of reflux do not usually require invasive esophageal evaluation. These patients generally benefit from an initial empiric trial of acid-suppression therapy. A clinical diagnosis of GERD can be assumed in patients who respond to appropriate therapy. Further diagnostic evaluation is useful to prevent misdiagnosis, identify complications, and assess treatment failures. Diagnostic tests should be performed in those patients who do not respond to therapy and for those who present with alarm symptoms (e.g., dysphagia, odynophagia, weight loss), which may be more indicative of more complicated disease.

2. Useful tests in diagnosing GERD include endoscopy, ambulatory pH or impedance monitoring, and manometry. A camera-containing capsule swallowed by the patient offers the newest technology for visualizing the esophageal mucosa via endoscopy. The PillCam ESO is less invasive than traditional endoscopy and takes less than 15 minutes to perform in the clinician’s office. Images of the esophagus are downloaded through sensors placed on the patient’s chest that are connected to a data collector. The camera-containing capsule is later eliminated in the stool. Endoscopy is not useful as a screening tool for Barrett esophagus and esophageal adenocarcinoma for patients with long-standing GERD. Unfortunately, the presence or absence of mucosal damage does not prove the patient’s symptoms are reflux related; for that, ambulatory pH monitoring is useful. Ambulatory pH monitoring can be performed by passing a small pH probe transnasally and placing it approximately 5 cm above the LES. Patients are asked to keep a diary of symptoms that later are correlated with the pH measurement corresponding to the time the symptom was reported.

Two recent developments related to ambulatory reflux monitoring include (1) the use of combined impedance–pH monitoring and (2) a wireless method of pH monitoring. Whereas ambulatory pH monitoring only measures acid reflux, combined impedance–pH monitoring measures both acid and nonacid reflux. The wireless pH-monitoring involves attaching a radio-telemetry capsule to the esophageal mucosa. The advantages of this method are that a longer period of monitoring is possible (48 hours), it may demonstrate superior recording accuracy compared with some catheter designs, and it is more comfortable for the patient because a nasogastric tube is unnecessary. Proton pump inhibitor therapy should be withheld for 7 days prior to performing ambulatory catheter pH, impedance–pH, or wireless pH monitoring when evaluating patients who have failed an initial empiric therapy and who have normal findings on endoscopy and manometry.

**CLINICAL CONTROVERSY**

Professional organizations differ in their recommendation for or against endoscopy as a screening tool for patients with chronic symptoms of GERD for the purpose of detecting Barrett esophagus and thereby reducing the risk of esophageal adenocarcinoma.

**CLINICAL PRESENTATION OF GERD**

**Symptom-based esophageal GERD syndromes (with or without esophageal tissue injury)**

Typical symptoms (May be aggravated by activities that worsen gastroesophageal reflux such as recumbent position, bending over, or eating a meal high in fat.)

- Heartburn (hallmark symptom described as a substernal sensation of warmth or burning rising up from the abdomen that may radiate to the neck. May be waxing and waning in character.)
- Water brash (hypersalivation)
- Belching
- Regurgitation

Alarm symptoms (These symptoms may be indicative of complications of GERD such as Barrett esophagus, esophageal strictures, or esophageal adenocarcinoma.)

- Dysphagia
- Odynophagia

**Tissue injury-based esophageal GERD syndromes (with or without esophageal symptoms)**

Symptoms (May present with alarm symptoms such as dysphagia, odynophagia or unexplained weight loss.)

- Esophagitis
- Strictures
- Barrett esophagus
- Esophageal adenocarcinoma

**Extraeosophageal GERD syndromes**

Symptoms (These symptoms have an association with GERD, but causality should only be considered if a concomitant esophageal GERD syndrome is also present.)

- Chronic cough
- Laryngitis
- Asthma
- Dental enamel erosion

Diagnostic tests for GERD

Clinical history

- Generally sufficient to clinically diagnose GERD for patients with typical symptoms.
- Endoscopy
  - Preferred for assessing the mucosa for esophagitis, identifying Barrett esophagus and diagnosing complications.
  - Non-inflammatory GERD and major motor disorders may be missed by endoscopy.
If no erosions, does not definitively show symptoms are GERD-related.

Ambulatory pH monitoring
- Identifies patients with excessive esophageal acid exposure and helps determine if symptoms are acid-related.
- Useful for patients not responding to acid-suppression therapy.
- Documents the percentage of time the intraesophageal pH is <4 and determines the frequency and severity of reflux.
- Measures only acid reflux (not nonacid reflux).
- Combined impedance–pH monitoring
- Measures both acid and nonacid reflux.

Manometry
- Ensure proper placement of esophageal pH probes (The recent advancement of the tubeless pH monitoring system using endoscopic landmarks for placement may negate the need for manometry for ensuring proper placement of esophageal pH probes.)
- Evaluate esophageal peristalsis and motility prior to antireflux surgery

Empiric trial of a proton pump inhibitor as a diagnostic test for GERD
- Less expensive and more convenient than ambulatory pH monitoring but lack standardized dosing regimen and duration of the diagnostic trial.

Barium radiography
- Not routinely used to diagnose GERD because lacks sensitivity and specificity; cannot identify Barrett esophagus.

Data from reference 2.

### TREATMENT

Therapeutic modalities used in the treatment of gastroesophageal reflux are targeted at reversing the various pathophysiologic abnormalities.

**DESIRED OUTCOMES**

3. The goals of treatment are to (1) alleviate or eliminate the patient’s symptoms, (2) decrease the frequency or recurrence and duration of gastroesophageal reflux, (3) promote healing of the injured mucosa, and (4) prevent the development of complications. Therapy is directed at augmenting defense mechanisms that prevent reflux and/or decrease the aggressive factors that worsen reflux or mucosal damage (Fig. 39-1). Therapy is directed at (1) decreasing the acidity of the refluxate, (2) decreasing the gastric volume available to be refluxed, (3) improving gastric emptying, (4) increasing LES pressure, (5) enhancing esophageal acid clearance, and (6) protecting the esophageal mucosa.

**GENERAL APPROACH TO TREATMENT**

4. The treatment of GERD is categorized into one of the following modalities: (1) lifestyle modifications and patient-directed therapy with antacids, nonprescription H₂-receptor antagonists, and/or nonprescription proton pump inhibitors; (2) pharmacologic intervention with prescription-strength acid-suppression therapy; (3) and antireflux surgery (Table 39-2). The initial therapeutic modality used is in part dependent on the patient’s condition (frequency of symptoms, degree of esophagitis, and presence of complications) (Table 39-3). Historically, a step-up approach was used, starting with noninvasive lifestyle modifications and patient-directed therapy and progressing to pharmacologic management or antireflux surgery. A step-down approach, starting with a proton pump inhibitor given once or twice daily instead of an H₂-receptor antagonist and then stepping down to the lowest dose of acid suppression (either an H₂-receptor antagonist or proton pump inhibitor) needed to control symptoms, is also effective. Neither the step-up nor the step-down approach has superior efficacy over the other. The clinician should determine the most appropriate approach for the individual patient. Every attempt should be made to aggressively control symptoms and to prevent relapses early in the course of the patient’s disease in order to prevent the complications. For patients with moderate to severe GERD, especially those with erosive disease, starting with a proton pump inhibitor as initial therapy is advocated because of its superior efficacy over H₂-receptor antagonists.

While weight loss in obese patients and elevation of the head of the bed have proven beneficial for most GERD patients, recommending all lifestyle modifications to all patients is not recommended. Instead, education on lifestyle modifications should be tailored to the individual needs of the patient. Table 39-4 lists many of the lifestyle modifications that can be recommended.

4. Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks should seek medical attention and are generally started on empiric therapy consisting of an acid-suppression agent. Acid-suppression therapy with proton pump inhibitors or H₂-receptor antagonists is the mainstay of GERD treatment. Patients presenting with moderate to severe symptoms (with or without esophageal erosions) should be started on a proton pump inhibitor as initial therapy because it provides the most rapid symptomatic relief and healing in the highest percentage of patients. H₂-Receptor antagonists in divided doses are effective for patients with milder GERD symptoms. Standard H₂-receptor antagonist doses may be increased to 2 to 4 times the normal dose for patients who do not respond to standard doses. However, if this is necessary, it is more cost-effective and efficacious to switch to a proton pump inhibitor.
Promotility agents are not as effective as acid-suppression agents. Combining promotility agents with acid-suppression drugs offers only modest improvements in symptoms over standard doses of H₂-receptor antagonists and should not be routinely recommended. In addition, the availability of a promotility agent that has an acceptable adverse effect profile is lacking. Mucosal protectants, such as sucralfate, have a very limited role in the treatment of GERD. Maintenance therapy is generally necessary to control symptoms and to prevent complications. For patients with more severe symptoms (with or without esophageal erosions) or for patients with other complications, maintenance therapy with a proton pump inhibitor is most effective. Routine use of combination therapy has no role in maintenance therapy of GERD. GERD that is refractory to adequate acid suppression is uncommon. In these cases, the diagnosis should be confirmed through further diagnostic tests before long-term, high-dose therapy or antireflux surgery are considered.¹

### NONPHARMACOLOGIC THERAPY

Nonpharmacologic treatment of GERD includes lifestyle modifications and antireflux surgery, which may be viable maintenance modalities in select patients. Endoscopic therapies, such as endoscopic sewing devices and endoluminal application of radio-frequency heat energy, have fallen out of favor and not routinely recommended.

#### Lifestyle Modifications

The most common lifestyle modifications that a patient should be educated about include weight loss in obese patients and elevation of the head of the bed, especially for those patients who have symptoms while in a recumbent position. Other lifestyle modifications should be individualized based on the patient’s specific situation. These include consumption of smaller meals and not eating 3 hours prior to sleeping, avoidance of foods or medications that exacerbate GERD; smoking cessation, avoidance of tight-fitting clothes, and avoidance of alcohol (Table 39–4).

Obesity increases the risk of GERD, most likely through increased intraabdominal pressure and possibly by disruption of the esophagogastric junction.¹² A high-fat meal will decrease LES pressure for 2 hours or more postprandially. In contrast, a high-protein, low-fat meal will elevate LES pressure. Consequently, weight loss and a low-fat diet may help to improve GERD symptoms. Elevating the head of the bed approximately 6 to 8 inches with a foam wedge under the mattress (not just elevating the head with pillows) decreases nocturnal esophageal acid contact time and should be recommended. Many foods may worsen the symptoms of GERD. Fats and chocolate can decrease LES pressure, whereas citrus juice, tomato juice, coffee, and pepper may irritate damaged endothelium.

It is important to evaluate patient profiles and to identify potential medications that may exacerbate GERD symptoms. Medications, such as anticholinergics, barbiturates, calcium channel blockers, and theophylline decrease LES pressure. Other medications, including aspirin, iron, nonsteroidal antiinflammatory drugs, quinidine, potassium chloride, and bisphosphonates can act as direct contact irritants to the esophageal mucosa. Patients taking bisphosphonates (e.g., alendronate) should be instructed to drink 6 to 8 oz of plain tap water and remain upright for at least 30 minutes following administration. Proper patient education can help prevent dysphagia or esophageal ulceration. Patients should be closely monitored for worsening symptoms when any of these medications are started. If symptoms worsen, alternative therapies may be warranted. The clinician must weigh the risks and benefits of continuing a drug known to worsen GERD and esophagitis.

Smoking can cause aerophagia, which leads to increased belching and regurgitation. However, data are lacking to show that symptoms improve for patients who quit smoking. Nevertheless, patients with GERD should be encouraged to quit smoking. Alcohol, although not thought to play a role in severe disease, decreases LES pressure and may exacerbate symptoms such as heartburn.

Many patients are noncompliant with lifestyle modifications, and even those who do comply generally continue to have symptoms that require acid-suppression therapy. Nonetheless, it is important to regularly stress the potential benefits of lifestyle modifications that would benefit each individual patient.

#### Interventional Approaches

Interventional approaches include antireflux surgery and endoscopic therapies.

**Antireflux Surgery**

Surgical intervention is a viable maintenance alternative for select patients with well-documented GERD.¹ The goal of antireflux surgery is to re-establish the antireflux barrier, to position the lower esophageal sphincter within the abdomen where it is under positive (intraabdominal) pressure, and to close any associated hiatal defect. Antireflux surgery should be considered for patients (1) who fail to respond

---

¹Level of evidence: I, strong evidence from at least one published systematic review of multiple, well-designed, randomized, controlled trials; II, strong evidence from at least one published, properly designed, randomized, controlled trial of appropriate size and in an appropriate clinical setting; III, strong evidence from published, well-designed trials without randomization, single group, pre–post, cohort, time series, or matched case-controlled studies; IV, evidence from well-designed nonexperimental studies from more than one center or research group or opinion of respected authorities, based on clinical evidence, descriptive studies, or reports of expert consensus committees.

Data from reference 4.
with an H₂-receptor antagonist or a promotility agent. In a 7-year follow-up study of omeprazole compared with antireflux surgery for patients with esophagitis, symptoms (regurgitation and heartburn) were better controlled in the surgical group; however treatment failures were also higher in the surgical group. In addition, more patients in the surgical group complained of complications, such as inability to belch, flatulence, and dysphagia. Long-term effectiveness of antireflux surgery is uncertain.

**Endoscopic Therapies** Endoscopic approaches for the management of GERD have included endoscopic sewing devices and endoluminal application of radiofrequency heat energy resulting in tissue injury or nerve ablation (the Stretta procedure). Unfortunately, results from these endoscopic therapies have proven to be less effective than pharmacologic treatment, and they carry a risk of complications such as infection, bleeding, and perforation. Additionally, the long-term efficacy and durability of these procedures are still being evaluated.

**Table Notes:**
- **Antacids:**
  - Maalox or Mylanta 30 mL as needed or after meals and at bedtime
  - Gaviscon 2 tabs after meals and at bedtime
  - Calcium carbonate 500 mg, 2–4 tablets as needed
  - **Nonprescription H₂-receptor antagonists (taken up to twice daily):**
    - Cimetidine 200 mg
    - Famotidine 10 mg
    - Nizatidine 75 mg
    - Ranitidine 75 mg
  - **Nonprescription proton pump inhibitor (taken once daily):**
    - Omeprazole 20 mg
    - Lansoprazole 15 mg
- **Proton pump inhibitors:**
  - Dexlansoprazole 30 mg, 60 mg daily
  - Esomeprazole 20–40 mg daily
  - Lansoprazole 30 mg daily
  - Omeprazole 20 mg daily
  - Rabeprazole 20 mg daily
  - Pantoprazole 40 mg daily
  - **High-dose H₂-receptor antagonist (for 8–12 weeks):**
    - Cimetidine 400 mg four times daily or 800 mg twice daily
    - Famotidine 40 mg twice daily
    - Nizatidine 150 mg four times daily
    - Ranitidine 150 mg four times daily

**Interventional Therapies:**
- Antireflux surgery
disappointing and are not routinely recommended. Emergence of natural orifice transluminal surgery (NOTES) and surgical techniques may evolve.

PHARMACOLOGIC THERAPY

Pharmacologic treatment consists of (1) patient-directed therapy with nonprescription antacids, H₂-receptor antagonists, or proton pump inhibitors and (2) prescription-strength acid-suppression therapy or promotility medications.

Patient-Directed Therapy

Patient-directed therapy, where patients self-treat themselves with nonprescription medications, is appropriate for mild, intermittent symptoms. Patients with continuous symptoms lasting longer than 2 weeks should seek medical attention.

Antacids and Antacid–Alginic Acid Products

Patients should be educated that antacids are an appropriate component of treating milder GERD symptoms, even though documentation of their efficacy in placebo-controlled clinical trials is lacking. Although the literature is somewhat controversial on the superiority of antacids to placebo, clinicians and patients clearly consider antacids to be effective for immediate symptomatic relief, and antacids are often used concurrently with other acid-suppression therapies. Maintaining the intragastric pH >4 decreases the activation of pepsinogen to pepsin, a proteolytic enzyme. Also, neutralization of gastric fluid leads to increased LES pressure. Patients who require frequent use of antacids for chronic symptoms should be treated with prescription-strength acid-suppression therapy because their illness is considered more significant.

An antacid product combined with alginic acid is not a potent neutralizing agent and does not enhance LES pressure; however, it does form a highly viscous solution that floats on the surface of the gastric contents. This viscous solution is thought to serve as a protective barrier for the esophagus against reflux of gastric contents. It also reduces the frequency of the reflux episodes. The combination product may be superior to antacids alone in relieving the symptoms of GERD. Efficacy data indicating endoscopic healing are lacking.

Antacid or antacid combination products may cause gastrointestinal adverse effects (diarrhea or constipation, depending on the product), alterations in mineral metabolism, and acid–base disturbances. Aluminum-containing antacids may bind to phosphate in the gut and lead to bone demineralization. In addition, antacids interact with a variety of medications by altering gastric pH, increasing urinary pH, adsorbing medications to their surfaces, providing a physical barrier to absorption, or forming insoluble complexes with other medications. Antacids have clinically significant drug interactions with tetracycline, ferrous sulfate, isoniazid, quinidine, sulfonylureas, and quinolone antibiotics. Antacid–drug interactions are influenced by composition, dose, dosage schedule, and formulation of the antacid.

Dosage recommendations for antacids in the management of GERD are somewhat difficult to derive from the literature. Doses range from hourly to an as-needed basis (Table 39–3). In general, antacids have a short duration of action, which necessitates frequent administration throughout the day to provide continuous neutralization of acid. Taking antacids after meals can increase the duration of action from about 1 hour to 3 hours; however, nighttime acid suppression cannot be maintained with bedtime doses.

Nonprescription H₂-Receptor Antagonists and Proton Pump Inhibitors

Nonprescription H₂-receptor antagonists (cimetidine, famotidine, nizatidine, and ranitidine) are effective in diminishing gastric acid secretion when taken prior to meals and decrease GERD symptoms associated with exercise. Antacids may have a slightly faster onset of action, while the H₂-receptor antagonists have a much longer duration of action compared with antacids.

The proton-pump inhibitor omeprazole is available without a prescription. A dose of 20 mg/day is indicated for short-term treatment of heartburn. Lansoprazole 15 mg gives patients a second option in the proton pump inhibitor class that is now available without a prescription. Patients who do not respond to lifestyle modifications and patient-directed therapy after 2 weeks should be seen by their clinician.

Acid-Suppression Therapy

Acid-suppression therapy with prescription-strength H₂-receptor antagonists and proton pump inhibitors are the mainstay of GERD treatment.

H₂-Receptor Antagonists (Cimetidine, Famotidine, Nizatidine, and Ranitidine) H₂-Receptor antagonists in divided doses are effective in treating patients with mild to moderate GERD. The majority of the trials assessing the efficacy of standard doses of H₂-receptor antagonists indicate that symptomatic improvement is achieved in an average of 60% of patients after 12 weeks of therapy. However, endoscopic healing rates tend to be lower, an average of 50% of patients at 12 weeks.

The efficacy of H₂-receptor antagonists in the management of GERD is extremely variable and is frequently lower than desired. Response to the H₂-receptor antagonists is dependent on the (1) severity of disease, (2) dosage regimen used, and (3) duration of therapy. These factors are important to keep in mind when comparing clinical trials and/or assessing a patient’s response to therapy. The severity of esophagitis at baseline has a profound impact on the patient’s response to H₂-receptor antagonists. For symptomatic relief of mild GERD, low-dose, nonprescription H₂-receptor antagonists or standard doses given twice daily may be beneficial. Patients who do not respond to standard doses may
Proton Pump Inhibitors (Dexlansoprazole, Esomeprazole, Lansoprazole, Omeprazole, Pantoprazole, and Rabeprazole) Proton pump inhibitors are superior to \( H_2 \)-receptor antagonists in treating patients with moderate to severe GERD. This includes not only those patients with esophageal tissue injury (e.g., Barrett esophagus, strictures, or esophagitis), but also those patients with symptom-based GERD syndromes. A few trials have compared proton pump inhibitors with each other. In general, healing rates at 4 weeks and 8 weeks are similar; lansoprazole and rabeprazole, however, may relieve symptoms faster after the first dose when compared with omeprazole. Healing rates at 4 weeks and 8 weeks were similar. Symptomatic relief is seen in approximately 83% of patients with endoscopic evidence of injury after 8 weeks treated with a proton pump inhibitor, whereas the endoscopic healing rate at 8 weeks is 78%. Proton pump inhibitors block gastric acid secretion by inhibiting gastric \( H^+/K^+ \)-adenosine triphosphatase in gastric parietal cells. This produces a profound, long-lasting antisecretory effect capable of maintaining the gastric pH >4, even during postprandial acid surges. A correlation appears to exist between the percentage of time the gastric pH remains >4 during the 24-hour period and healing erosive esophagitis.

The proton pump inhibitors are usually well-tolerated. Potential adverse effects include headache, dizziness, somnolence, diarrhea, constipation, nausea, and vitamin \( B_{12} \) deficiency. The frequency of adverse events appears to be similar to that seen with the \( H_2 \)-receptor antagonists. Of recent concern is the role proton pump inhibitors may play in the acquisition of \( C. difficile \) infection during acid suppression. Acid suppression may result in loss of host defense against ingested spores and bacteria permitting a higher burden of exposure. Patient selection is important to minimize this risk.

Drug interactions with the proton pump inhibitors vary slightly with each agent. All proton pump inhibitors can decrease the absorption of drugs such as ketoconazole or itraconazole, which require an acidic environment to be absorbed. All proton pump inhibitors are metabolized by the cytochrome P450 system to some extent, specifically by the CYP2C19 and CYP3A4 enzymes. While, no interactions with lansoprazole, pantoprazole, or rabeprazole have been seen with CYP2C19 substrates such as diazepam, warfarin, and phenytoin, concerns have been raised regarding the concomitant use of proton pump inhibitors, especially omeprazole, with clopidogrel. Clopidogrel, a prodrug, is converted to its active metabolite via the CYP2C19 and CYP3A4 enzyme. Inhibition of CYP2C19 by proton pump inhibitors may decrease the effectiveness of clopidogrel causing cardiovascular adverse events. Further evaluation is needed to determine the extent of this drug interaction and the role polymorphic gene variation may play in patients on clopidogrel. In the mean time, careful review of the risk-to-benefit profile regarding the use of proton pump inhibitors for patients on clopidogrel should be considered. Using an alternative agent, such as an \( H_2 \)-receptor antagonist may be prudent in this patient population.

Esomeprazole does not appear to interact with warfarin or phenytoin, and an interaction with diazepam is generally not considered clinically relevant. Pantoprazole is also metabolized by a cytosolic sulfotransferase and is therefore less likely to have significant drug interactions compared with the other proton pump inhibitors. Although generally not a problem, omeprazole has the potential to inhibit the metabolism of warfarin, diazepam, and phenytoin, and lansoprazole may decrease theophylline concentrations. Patients taking warfarin should be monitored for potential bleeding. Drug interactions with omeprazole are of particular concern for patients who are considered “slow metabolizers” of omeprazole, which is more common in the Asian population and also found in approximately 3% of the Caucasian population. Unfortunately, it is unclear which patients have the polymorphic gene variation that makes them slow metabolizers. Like omeprazole, the metabolism of esomeprazole may also be altered for patients with this polymorphic gene variation. Patients on potentially interacting drugs, such as warfarin, should be monitored closely for potential problems.

The proton pump inhibitors degrade in acidic environments and are therefore formulated in a delayed-release capsule or tablet formulation. Lansoprazole, esomeprazole, and omeprazole contain enteric-coated (pH-sensitive) granules in a capsule form. For patients who are unable to swallow the capsule or for pediatric patients, the contents of the delayed-release capsule can be mixed in applesauce or placed in orange juice. If a patient has a nasogastric tube, the contents of an omeprazole capsule can be mixed in 8.4% sodium bicarbonate solution. Esomeprazole granules can be dispersed in water. Lansoprazole comes in a packet for oral suspension and a delayed-release, orally disintegrating tablet. Although these dosage forms are beneficial for those who cannot swallow the capsule, such as elderly or pediatric patients, the packet for oral suspension should not be placed through a nasogastric tube. Patients taking pantoprazole or rabeprazole should be instructed not to crush, chew, or split the delayed-release tablets. Lansoprazole, esomeprazole, and pantoprazole are available in an intravenous formulation, which offers an alternative route of administration for patients who are unable to take an oral proton pump inhibitor. Importantly, the intravenous product is not more efficacious than oral proton pump inhibitors and is significantly more expensive. Careful patient selection is necessary to avoid the increased cost from the use of the intravenous product.
The newest dosage form of omeprazole is in a delayed-release tablet and a combination product with sodium bicarbonate in an immediate-release capsule and oral suspension (Zegerid). It is the first immediate-release proton pump inhibitor and should be taken on an empty stomach at least 1 hour before a meal. Zegerid offers an alternative to the delayed-release capsules or the intravenous formulation in adult patients with a nasogastric tube.

Dexlansoprazole is the newest proton pump inhibitor approved by the FDA. The capsule is a dual delayed-release formulation, with the first release occurring 1 to 2 hours after the dose and the second release occurring 4 to 5 hours after the dose. The clinical significance of this dual release is not known.

Patients should be instructed to take their proton pump inhibitor in the morning, 15 to 30 minutes before breakfast, to maximize efficacy, because these agents inhibit only actively secreting proton pumps. Dexlansoprazole can be taken without regard to meals. Patients with nocturnal symptoms may benefit from taking their proton pump inhibitor prior to the evening meal. If dosed twice daily, the second dose should be administered approximately 10 to 12 hours after the morning dose and prior to a meal or snack.

**Promotility Agents**

Promotility agents may be useful as an adjunct to acid-suppression therapy for patients with a known motility defect (e.g., LES incompetence, decreased esophageal clearance, delayed gastric emptying). Unfortunately, all available promotility agents are fraught with undesirable side effects and are not generally as effective as acid-suppression therapy. Extrapyramidal effects, sedation, and irritability are common with bethanechol and metoclopramide.

**Cisapride** Cisapride has comparable efficacy to H₂-receptor antagonists in treating patients with mild esophagitis. Unfortunately, cisapride is no longer available for routine use because of life-threatening cardiac arrhythmias when it is combined with certain medications and other disease states. It is currently available only through a limited access program from the manufacturer.

**Metoclopramide** Metoclopramide, a dopamine antagonist, increases LES pressure in a dose-related manner, and accelerates gastric emptying in gastroesophageal reflux patients. Unlike cisapride, however, metoclopramide does not improve esophageal clearance. Metoclopramide provides symptomatic improvement for some patients with gastroesophageal reflux disease; however, substantial data indicating that metoclopramide provides endoscopic healing are lacking. In addition, metoclopramide’s side-effect profile and the incidence of tachyphylaxis with continued use limits its usefulness in treating many patients with GERD. The risk of adverse effects is much greater for elderly patients and for patients with renal dysfunction because the drug is primarily eliminated by the kidneys. Contraindications include Parkinson disease, mechanical obstruction, concomitant use of other dopaminergic agents or anticholinergic agents, and pheochromocytoma.

**Bethanechol** Bethanechol, a promotility drug, has limited value in the treatment of GERD because of unwanted side effects. Bethanechol is not routinely recommended for the treatment of GERD.

**Other Promotility Drugs Under Investigation** Other promotility drugs under investigation include domperidone, a dopamine antagonist, itopride, and baclofen. Because domperidone does not cross the blood–brain barrier, it does not cause the central nervous system effects seen with metoclopramide. However, it is not currently available in the United States. Baclofen, an aminobutyric acid (GABA) receptor type B agonist, may decrease esophageal acid exposure and the number of reflux episodes by decreasing the number of transient relaxations of the LES. However, this agent has many side effects, limiting its usefulness in GERD.

**Mucosal Protectants**

Sucralfate, a nonabsorbable aluminum salt of sucrose octasulfate, has very limited value in the treatment of GERD. Sucralfate is not routinely recommended for use in the treatment of GERD.

**Combination Therapy**

Combination therapy with an acid-suppression agent and a promotility agent or a mucosal protectant would seem logical given the multifactorial nature of the disease, particularly in light of the disappointing results seen with many monotherapy regimens. However, sufficient data to support combination therapy are limited, and this approach should not be routinely recommended unless a patient has GERD plus motor dysfunction occurring. The addition of an H₂-receptor antagonist at bedtime to proton pump inhibitor therapy for the treatment of nocturnal symptoms has been evaluated. The effectiveness of this strategy may decrease over time due to tachyphylaxis with H₂-receptor antagonists.

**Maintenance Therapy**

Although healing and/or symptomatic improvement may be achieved via many different therapeutic modalities, a large percentage of patients with gastroesophageal reflux will relapse following discontinuation of therapy, especially those with more severe disease. Patients who have symptomatic relapse following discontinuation of therapy or lowering of dose, including patients with complications such as Barrett esophagus, strictures, or esophageal tumors, should be considered for long-term maintenance therapy to prevent complications or worsening of esophageal function. The goal of maintenance therapy is to improve quality of life by controlling the patient’s symptoms and preventing complications. These goals cannot generally be achieved by decreasing the dose of the therapeutic modality used for initial healing or switching to a less potent acid-suppression agent. Most patients will require standard doses to prevent relapses. Patients should be counseled on the importance of complying with lifestyle changes and long-term maintenance therapy in order to prevent recurrence or worsening of disease.

H₂-Receptor antagonists may be effective maintenance therapy for patients with mild disease. The proton pump inhibitors are the drugs of choice for maintenance treatment of moderate to severe esophagitis or symptoms. Low doses of a proton pump inhibitor or alternate-day dosing may be effective in some patients with milder symptoms, thereby allowing titration in some cases. “On-demand” maintenance therapy, by which patients take their proton pump inhibitor only when they have symptoms, may be effective for patients with endoscopy-negative GERD. Although not well studied, many patients with only mild to moderate symptoms may decide on their own to take their medication this way for the financial benefit. However, patients with more-persistent symptoms and/or complications should be maintained on standard doses of proton pump inhibitors.

Long-term chronic use of proton pump inhibitor doses higher than standard treatment doses is not indicated unless the patient has complicated symptoms, has erosive esophagitis per endoscopy, or has had further diagnostic evaluation to determine the level of acid exposure. Metoclopramide is not approved for maintenance therapy, and use is limited by adverse-effect profile. Antireflux surgery may also be considered a viable alternative to long-term drug therapy for maintenance of healing for patients who are candidates.
Maintenance Therapy with H₂-Receptor Antagonists  The studies evaluating the efficacy of the H₂-receptor antagonists in maintaining GERD patients in remission have been disappointing. Currently, ranitidine 150 mg twice daily is the only H₂-receptor antagonist regimen that is FDA approved for maintenance of healing of erosive esophagitis.

Maintenance Therapy with Proton Pump Inhibitors  Long-term use of the proton pump inhibitors are relatively safe, with no evidence of carcinoid tumors directly linked to their use. Prolonged hypergastrinemia leading to the development of colonic polyps, and potentially adenocarcinoma, was also a concern that has proven unfounded with long-term use.21 However, the role of Helicobacter pylori status for patients with GERD has been questioned. As a consequence of the controversy surrounding H. pylori and GERD, specific guidelines on how to handle these patients are lacking. Most clinicians would probably opt to eradicate H. pylori infections once detected. Further studies are needed to determine the role of H. pylori for patients with GERD. Concern has been raised about the long-term use of proton pump inhibitors and the increased risk of bone fractures.21 Data are conflicting, but the proposed mechanism is through inhibition by the H⁺/K⁺-ATPase pump indirectly inhibiting bone resorption. In addition, the increased pH may decrease calcium absorption, thereby putting patients at greater risk for fractures.24,25

SPECIAL POPULATIONS

There are several special populations that should be considered when discussing GERD, such as patients with atypical symptoms, pediatric patients, elderly patients, and patients with refractory symptoms.

PATIENTS WITH EXTRAESOPHAGEAL (ATYPICAL) GERD

Patients presenting with atypical symptoms may require higher doses and longer treatment courses as compared with patients with typical symptoms. Patients with suspected reflux chest pain syndrome may benefit from an empiric course of twice daily proton pump inhibitor therapy for 4 weeks once cardiac work up is known to be negative.1 If symptoms continue, patients should be evaluated with manometry, ambulatory pH, or impedance-pH monitoring to rule out dysmotility or refractory symptoms.1 Because there are many causes of asthma and laryngeal symptoms, a concomitant esophageal GERD syndrome must also be present to associate these symptoms with GERD. In practice, these patients may benefit from twice daily proton pump inhibitor for 3 to 4 months even though evidence supporting this regimen is not well established.1 This recommendation is based more on pH monitoring data showing normalization of gastric pH with twice daily dosing.1 For patients not responding to empiric therapy, pH monitoring may be beneficial in determining acid exposure as it relates to symptoms. The optimal dose of proton pump inhibition is not well-defined. Maintenance therapy is generally indicated for patients who respond to the therapeutic trial or have endoscopic evidence of reflux. Antireflux surgery may be an option in select patients. Without a concomitant esophageal GERD syndrome, acid-suppressing therapy is not well supported for patients with laryngitis or asthma symptoms.

PEDIATRIC PATIENTS WITH GERD

Many infants have physiologic reflux with little or no clinical consequence. Uncomplicated gastroesophageal reflux usually manifests as regurgitation or “spitting up” and resolves without incident by 12 to 14 months of life.26 It usually responds to supportive therapy, including dietary adjustments, postural management, and reassurance for the parents. Thickened feedings may be useful in milder cases. While this does not decrease the time the pH is <4, it may decrease the incidence of regurgitation.26 Chronic vomiting associated with gastroesophageal reflux must be distinguished from other causes, such as neurologic, metabolic, eating, and rumination disorders. Smaller, more frequent feedings may be beneficial. In formula-fed infants, an extensively hydrolyzed protein may help identify milk protein sensitivity as the cause of unexplained vomiting and crying.26 Developmental immaturity of the LES is one suspected cause of gastroesophageal reflux in infants.26 Like adults, transient LES relaxations seem to be the most common cause of gastroesophageal reflux in children. Other causes include impaired luminal clearance of gastric acid, neurologic impairment, and type of infant formula. Complications, although rare, include distal esophagitis, failure to thrive, esophageal peptic strictures, Barrett esophagus, and pulmonary disease.

The benefits of using a promotility medication, such as metoclopramide, erythromycin, domperidone, bethanachol, and baclofen, are outweighed by the potential adverse effects that may occur and, therefore, cannot be routinely recommended.26 Ranitidine is commonly used at a dose of 2 mg/kg twice daily.26 Tachyphylaxis may develop making the effectiveness of H₂-receptor antagonists less than optimal. The use of proton pump inhibitor use in children is increasing, especially in those with esophagitis. Most patients will respond to once daily proton pump inhibitor dosing. Lansoprazole, esomeprazole and omeprazole are indicated for treating symptomatic and erosive GERD for pediatric patients older than age 1 year. Lansoprazole 15 mg once daily is recommended for children who weigh 30 kg or less, and a dose of 30 mg once daily is recommended for those who weigh more than 30 kg. Esomeprazole may be dosed 10 to 20 mg daily for children 1 to 11 years old and 20 to 40 mg daily for children 12 to 17 years old. Omeprazole 5 mg daily may be used in children weighing between 5 to 10 kg, 10 mg for children weighing between 10 to 20 kg and 20 mg daily for children weighing >20 kg. Even though no major adverse events have been noted in children receiving proton pump inhibitors for up to 7 years, the relative safety of prolonged proton pump inhibitor use in children remains unknown.27 Long-term use of a proton pump inhibitor without a clear diagnosis of GERD is not recommended.26

ELDERLY PATIENTS WITH GERD

Many elderly patients have decreased host defense mechanisms, such as saliva production. More aggressive therapy with a proton pump inhibitor may be warranted for patients older than 60 years of age with symptomatic GERD. Often these patients do not seek medical attention because they feel their symptoms are part of the normal aging process. They may also present with atypical symptoms such as chest pain, asthma, poor dentition, or jaw pain. Decreased GI motility is a common problem in elderly patients. Unfortunately, there are no good promotility agents available to these patients. Elderly patients are especially sensitive to the central nervous system effects of metoclopramide. They may also be sensitive to the central nervous system effects of H₂-receptor antagonists. Proton pump inhibitors appear to be the most useful treatment modality because they have superior efficacy and are dosed once daily, which is beneficial in all patients, but is especially beneficial in the elderly. Long-term risk of bone fractures may be of concern in this population. Patients at risk for bone fractures should be monitored appropriately.

PATIENTS WITH REFRACTORY GERD

GERD refractory to medical management is rare. Other causes for the patient’s symptoms should be evaluated. The majority of patients with refractory symptoms experience nocturnal acid...
breakthrough. Other reasons for refractory symptoms may be related to timing of proton pump inhibitor and drug metabolism differences in certain patients. Because of this, switching to another proton pump inhibitor may be effective for refractory symptoms in some patients. Ambulatory pH monitoring is useful for patients who are not responding to therapy. Adding an H₂-receptor antagonist at bedtime for nocturnal symptoms has been suggested; however, the effect may be short-lived. Antireflux surgery may also be considered in this patient population.

**PHARMACOECONOMIC CONSIDERATIONS**

In addition to the traditional clinical endpoints that demonstrate that a certain therapy is effective, the cost effectiveness of the therapy in relation to predicted outcomes and its effects on quality of life must be evaluated. For GERD, one must consider the primary goals of treatment: to relieve symptoms, to heal injury, to prevent recurrence, and to prevent complications. These factors must be evaluated separately, because different costs are associated with achieving each end point. For example, patients with complications associated with GERD, such as strictures, would be more likely to use medical resources as a consequence of revisits and diagnostic tests. Although effects on quality of life may be difficult to evaluate when your goal is preventing recurrence, untreated GERD has a more negative impact on psychological well-being than untreated hypertension, mild heart failure, angiina pectoris, or menopause. Improving a patient’s quality of life is a measure of treatment success and may help decide which therapy a patient receives.

The proton pump inhibitors are generally more expensive than the H₂-receptor antagonists or promotility agents. Omeprazole’s generic availability and nonprescription availability of omeprazole and lansoprazole makes this less of an issue. However, the most expensive therapy is the one that is ineffective. If the H₂-receptor antagonist does not accomplish the treatment goals, then it costs more because the patient must be retreated.

Patient compliance is another factor that affects the outcome of drug therapy. Drug regimens that are easily managed improve compliance, and thus improve outcome for the patient. This especially can be a problem for patients who require high-dose therapy with H₂-receptor antagonists. Not only is the patient required to take the drug more often in higher doses, but there is also increased expense associated with such regimens. The patient may be unable to afford the drug. Choosing a drug that is least expensive and provides the greatest benefit related to dosing interval and number of tablets taken is the optimal regimen. Studies comparing various treatment strategies for GERD show that proton pump inhibitors are more cost-effective than H₂-receptor antagonists, especially for patients with moderate to severe disease.

Decision analysis has been used to evaluate the cost-effectiveness of lifestyle modifications and/or patient-directed therapy alone or combined with omeprazole 20 mg daily or ranitidine 150 mg twice daily for patients with persistent symptomatic GERD. A complex model that evaluated the influence of empiric versus definitive therapy, compliance, and efficacy of the three treatment regimens was employed. Although the retail cost of omeprazole was highest among the treatments evaluated, it was the most cost-effective strategy and was associated with the lowest overall cost. Studies also show that proton pump inhibitors improve quality-of-life measures in symptomatic patients with erosive esophagitis. Additional studies are needed to evaluate the impact of various treatment regimens on quality-of-life issues and cost, and to compare long-term medical management with antireflux surgery and endoscopic therapies.

**EVALUATION OF THERAPEUTIC OUTCOMES**

The long-term benefits of treatment are difficult to assess because of the limited information known about the epidemiology and natural history of GERD. Consequently, successful outcomes are generally measured in terms of three separate end points: (1) relieving symptoms, (2) healing the injured mucosa, and (3) preventing complications.

The short-term goal of therapy is to relieve symptoms such as heartburn and regurgitation to the point at which they do not impair the patient’s quality of life. Patients should be educated regarding specific lifestyle modifications that are applicable to their individual situation including weight loss, raising the head of the bed, smoking cessation, eating smaller meals, and avoiding eating prior to bedtime. Patients should also be instructed to avoid or limit foods that aggravate GERD symptoms, such as fat and chocolate. In addition, the patient’s drug profile should be reviewed to identify medications that may contribute to GERD symptoms. These agents should be avoided if possible. Table 39–5 has recommendations for providing pharmaceutical care to patients with GERD.

The clinician should take an active role in educating the patient about potential adverse effects and drug interactions that may occur with drug therapy. The frequency and severity of symptoms should be monitored and patients should be counseled on symptoms that suggest the presence of complications requiring immediate medical attention, such as dysphagia or odynophagia. Patients should also be monitored for the presence of atypical symptoms such as laryngitis asthma or chest pain. These symptoms require further diagnostic evaluation. Long-term maintenance treatment is indicated for patients who have strictures because the strictures commonly recur if reflux esophagitis is not treated.

The second goal is to heal the injured mucosa. Again, individualized lifestyle modifications and the importance of complying with the therapeutic regimen chosen to heal the mucosa should be stressed. Patients should be educated about the risk of relapse and the need for long-term maintenance therapy to prevent recurrence or complications.

SECTION 4

Gastrointestinal Disorders
The final, more long-term goal of therapy is to decrease the risk of complications (esophagitis, strictures, Barrett esophagus, and esophageal adenocarcinoma). A small subset of patients may continue to fail treatment despite therapy with high doses of H$_2$-receptor antagonists or a proton pump inhibitor. Patients should be monitored for the presence of continual pain, dysphagia, or odynophagia.

**ABBREVIATIONS**

GERD: gastroesophageal reflux disease  
GI: gastrointestinal  
H$_2$: histamine type-2  
LES: lower esophageal sphincter

Peptic Ulcer Disease

ROSEMARY R. BERARDI AND RANDOLPH V. FUGIT

**KEY CONCEPTS**

1. Patients with peptic ulcer disease (PUD) should reduce psychological stress, cigarette smoking, and nonsteroidal antiinflammatory drug (NSAID) use and avoid foods and beverages that exacerbate ulcer symptoms.

2. Eradication is recommended for all *Helicobacter pylori* (*H. pylori*)–positive patients with an active ulcer, a documented history of a prior ulcer, or a history of ulcer-related complications.

3. The selection of an *H. pylori* eradication regimen should be based on efficacy, safety, antibiotic resistance, cost, and the likelihood of medication adherence. Treatment should be initiated with a proton pump inhibitor (PPI)–based three-drug regimen. If a second course of *H. pylori* therapy is required, the regimen should contain different antibiotics.

4. PPI cotherapy reduces the risk of NSAID-related gastric and duodenal ulcers and is at least as effective as recommended dosages of misoprostol and superior to the histamine-2 receptor antagonists (H2RA).

5. Standard PPI dosages and a nonselective NSAID are as effective as a selective cyclooxygenase-2 (COX-2) inhibitor in reducing the risk of NSAID-induced ulcers and upper gastrointestinal (GI) complications.

6. The eradication of *H. pylori* improves clinical outcomes and decreases the use of healthcare resources when compared with conventional antisecretory therapy. The cost effectiveness of misoprostol cotherapy is greatest for patients with the highest risk for GI complications. Cotherapy with PPIs and NSAIDs or selective COX-2 inhibitors is cost effective even in low-risk patients especially if the least costly PPI is used.

7. Patients with PUD, especially those receiving *H. pylori* eradication or misoprostol cotherapy, require patient education regarding their disease and drug treatment to successfully achieve a positive therapeutic outcome.

8. The recommended treatment for severe peptic ulcer bleeding after appropriate endoscopic treatment is the intravenous administration of a PPI loading dose followed by a 72-hour continuous infusion with a goal of maintaining an intragastric pH of 6 or greater.

9. Critically ill patients at the highest risk of developing stress-related mucosal bleeding (SRMB) who require prophylactic drug therapy include those with respiratory failure on mechanical ventilation or those with coagulopathy.

10. There are limited data to support the selection of a PPI over an intravenous H2RA for SRMB prophylaxis. The decision should be based upon appropriate individual patient characteristics (e.g., nothing by mouth, presence of nasogastric tube, renal failure).

**PEPTIC ULCER DISEASE**

Acid-related diseases (gastritis, erosions, and peptic ulcer) of the upper gastrointestinal (GI) tract require gastric acid for their formation.1–3 Peptic ulcer disease (PUD) differs from gastritis and erosions in that ulcers typically extend deeper into the muscularis mucosa.1 There are three common forms of peptic ulcers: *Helicobacter pylori* (*H. pylori*)–positive, nonsteroidal antiinflammatory drug (NSAID)-induced, and stress ulcers (Table 40–1). The term stress-related mucosal damage (SRMD) is preferred to stress ulcer or stress gastritis, because the mucosal lesions range from superficial gastritis and erosions to deep ulcers.

*H. pylori*–positive and NSAID-induced ulcers are chronic peptic ulcers that differ in etiology, clinical presentation, and tendency to recur (see Table 40–1). These ulcers develop most often in the stomach and duodenum of ambulatory patients (Fig. 40–1). Occasionally, ulcers develop in the esophagus, jejunum, ileum, or colon. The natural course of chronic PUD is characterized by frequent ulcer recurrence. The most important factors that influence ulcer recurrence are *H. pylori* infection and NSAID use. Other factors include cigarette smoking, alcohol use, ulcer-related complications, gastric acid hypersecretion, and patient noncompliance. The cause of ulcer recurrence is most likely multifactorial.

Peptic ulcers are also associated with Zollinger-Ellison syndrome (ZES), radiation, chemotherapy, vascular insufficiency, and other chronic diseases (Table 40–2).1,3 Although a strong association exists between chronic pulmonary diseases, chronic renal failure, and cirrhosis, the pathophysiologic mechanisms of these associations remain unclear.1 In contrast, SRMD occurs primarily in the stomach in critically ill patients (see Table 40–1).1

This chapter focuses on chronic PUD associated with *H. pylori* and NSAIDs. A brief discussion of ZES and upper GI bleeding related to PUD and SRMD is included.

**EPIDEMIOLOGY**

The epidemiology of PUD is complicated and difficult to estimate given the variability in the prevalence of H. pylori infection, NSAID use, and cigarette smoking as well as the various methods used to detect ulcers, e.g., endoscopy, radiology, symptoms, or complications. The prevalence and incidence of PUD in the United States also reflects improvements in drug therapy, the dramatic shift to ambulatory management, and changes in the criteria and coding system for mortality and hospitalization data. Recent trends suggest a shift from predominance in men to a similar occurrence in men and women with increasing rates of disease in older individuals and a decrease in the younger population. Despite a modest decline in mortality, hospitalizations, and office visits, PUD remains one of the most common GI diseases, resulting in impaired quality of life, work loss, and high-cost medical care.

**ETIOLOGY AND RISK FACTORS**

Most peptic ulcers occur in the presence of acid and pepsin when H. pylori, NSAIDs, or other factors (see Table 40–2) disrupt the normal mucosal defense and healing mechanisms. Hypersecretion of acid is the primary pathogenic mechanism in hypersecretory states such as ZES. Benign gastric ulcers can occur anywhere in the stomach, although most are located on the lesser curvature, just distal to the junction of the antral and acid-secreting mucosa (see Fig. 40–1). Most duodenal ulcers occur in the first part of the duodenum (duodenal bulb).

**HELICOBACTER PYLORI**

H. pylori infection causes chronic gastritis in infected individuals and is causally linked to PUD, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer (Fig. 40–2). The majority of infected individuals remain asymptomatic, but 10% to 20% will develop PUD during their lifetime and about 1% will develop gastric cancer. Host-specific cofactors and H. pylori strain variability play an important role in the pathogenesis of PUD and gastric cancer. Although an association between H. pylori and PUD bleeding is less clear, there is evidence that eradication of H. pylori decreases recurrent bleeding. No specific link has been established between H. pylori and dyspepsia, nonulcer dyspepsia (NUD), or gastroesophageal reflux disease (GERD). However, some patients with dyspepsia and NUD may benefit from H. pylori eradication. Although eradication of H. pylori may worsen GERD symptoms in some patients, eradication should not be withheld. An association between H. pylori infection and iron deficiency anemia has been established, but cause and effect has not been proven, and whether H. pylori eradication is beneficial is uncertain. There are insufficient data to support a link between H. pylori and extragastric manifestations including cardiovascular, hematologic, respiratory, hepatobiliary, and neurologic diseases.

The prevalence of H. pylori varies by geographic location, socioeconomic conditions, ethnicity, and age. In developing countries, H. pylori prevalence is more common than in industrialized countries and correlates with lower socioeconomic levels. The prevalence of H. pylori in the United States is 30% to 40% but is much higher in individuals over 60 years (50% to 60%) than in children under 12 years (10% to 15%) of age. Although most individuals in the United States acquire H. pylori in childhood, the rate of acquisition in children is declining and most likely will continue to fall as a consequence of improved socioeconomic conditions. Caucasians are infected with H pylori less frequently than African Americans and Hispanic persons, but this is thought to be related to lower socioeconomic status and living conditions. Infection rates do not differ with gender or smoking status.

**FIGURE 40-1. Anatomic structure of the stomach and duodenum and most common locations of gastric and duodenal ulcers.**
The natural history of *Helicobacter pylori* infection in the pathogenesis of gastric ulcer and duodenal ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric cancer.

The most common route of *H. pylori* transmission is person to person either by gastro–oral (vomitus) or fecal–oral (diarrhea) contact which occurs primarily during childhood. Members of the same household are likely to become infected when someone in the same household is infected. *H. pylori* can also be transmitted by the use of inadequately sterilized endoscopes.

### NONSTEROIDAL ANTINFLAMMATORY DRUGS

NSAIDs (Table 40–3) are widely used in the United States, particularly in individuals over 60 years of age, to treat chronic pain and inflammation. These agents include prescription and nonprescription medications and low-dose aspirin used for cardiovascular and cerebrovascular risk reduction. There is overwhelming evidence linking chronic NSAID (including aspirin) use to a variety of upper GI tract injuries. NSAIDs cause superficial (topical) mucosal damage consisting of petechiae (intramucosal hemorrhages) within minutes of ingestion, and progress to erosions with continued use. These lesions typically heal within a few days and rarely cause ulcers or acute upper GI bleeding. Gastrroduodenal ulcers develop in about 25% of chronic NSAID users with continued use. Gastric ulcers are most common, occur primarily in the antrum, and are of greater concern because of their potential to cause ulcer-related upper GI complications (see Table 40–1). As many as 2% to 4% of patients with an NSAID ulcer will bleed or perforate. Each year, NSAIDs account for at least 100,000 hospitalizations and between 7,000 and 10,000 deaths in the United States. NSAID-induced ulcers occur less frequently in the esophagus, small bowel, and colon. How NSAIDs damage the lower GI tract is unclear, but the enteropathy is associated with lower GI bleeding.

Table 40–4 lists the risk factors associated with NSAID-induced ulcers and upper GI complications. Combinations of factors confer an additive risk. Advanced age is an independent risk factor, and the incidence of NSAID-induced ulcers increases linearly with the age of the patient. The high incidence of ulcer complications in older individuals may be explained by age-related changes in gastric mucosal defense. The relative risk of NSAID complications is increased for patients with a previous peptic ulcer and may be as high as 14-fold in those with a history of an ulcer-related complication. The risk of adverse events is greatest during the first month after initiating continuous therapy and remains the same throughout treatment.

NSAID ulcers and related complications are dose-dependent, but may occur with low doses of nonprescription NSAIDs and low cardioprotective dosages of aspirin (81 to 325 mg/day). Factors such as NSAID potency, longer duration of effect, and a greater propensity to inhibit cyclooxygenase-1 (COX-1) versus COX-2 isoenzymes are associated with increased risk (see Table 40–3). NSAID-related dyspepsia, in itself, does not correlate directly with mucosal injury or clinical events. However, new-onset dyspepsia, changes in severity, or dyspepsia not relieved by antiulcer medications may suggest an ulcer or ulcer complication. Nonacetylated salicylates (e.g., salsalate) may be associated with decreased GI toxicity. Buffered or enteric-coated aspirin confers no added protection from upper GI events.

NSAID ulcer and GI complication risk are increased with the use of multiple NSAIDs or the concomitant use of low-dose aspirin, oral bisphosphonates, corticosteroids, anticoagulants, antiplatelet drugs, and selective serotonin reuptake inhibitors. The risk of an ulcer-related GI complication is greater when a NSAID or COX-2 inhibitor (see Table 40–3) is coadministered with low-dose aspirin than when either drug is taken alone. The NSAID may also reduce the antiplatelet effects of aspirin, although NSAIDs vary in their effects on platelet function. Corticosteroids, when used alone, do not potentiate the risk of ulcer or complications, but the relative risk is increased twofold in corticosteroid users who are

*Combinations of risk factors are additive.*

Data from references 1, 12 to 15, 20, and 26.
also taking concurrent NSAIDs. The relative risk of GI bleeding increases up to 20-fold when NSAIDs are taken concomitantly with anticoagulants (e.g., warfarin) and up to sixfold with the concurrent use of serotonin reuptake inhibitors. When clopidogrel is taken in combination with aspirin, an NSAID, or an anticoagulant, the risk of GI bleeding is increased compared with when these agents are taken alone. Even when prescribed as monotherapy, clopidogrel increases the risk of rebleeding for patients with history of a bleeding ulcer.

*H. pylori* and NSAIDs act independently to increase ulcer risk and ulcer-related bleeding and appear to have additive effects. Thus, the incidence of peptic ulcer is higher in *H. pylori*-positive NSAID users. Whether *H. pylori* infection is actually a risk factor for NSAID ulcers remains controversial. However, eradication is reported to reduce the incidence of ulcer if undertaken prior to starting the NSAID but does not reduce the risk for patients who were previously taking an NSAID.

**CIGARETTE SMOKING**

Epidemiologic evidence links cigarette smoking to PUD, but it is uncertain whether smoking causes peptic ulcers. Ulcer risk is proportional to the number of cigarettes smoked and is modest when fewer than 10 cigarettes are smoked per day. Cigarette smoking impairs ulcer healing, promotes ulcer recurrence, and increases ulcer risk. The exact mechanism by which cigarette smoking contributes to PUD remains unclear. Possible mechanisms include inhibition of pancreatic bicarbonate secretion and increases in gastric acid secretion, but these effects are inconsistent. Whether nicotine or other components of smoke are responsible for these physiologic alterations is unknown.

**PSYCHOLOGICAL STRESS**

The importance of psychological factors in the pathogenesis of PUD remains controversial. Clinical observation suggests that ulcer patients are adversely affected by stressful life events. However, results from controlled trials are conflicting and have failed to document a cause-and-effect relationship. Emotional stress may induce behavioral risks such as smoking and the use of NSAIDs or alter the inflammatory response or resistance to *H. pylori* infection. The role of stress and how it affects PUD is complex and probably multifactorial.

**DIETARY FACTORS**

The role of diet and nutrition in PUD is uncertain. Coffee, tea, cola beverages, beer, milk, and spices may cause dyspepsia but do not increase the risk for PUD. Beverage restrictions and bland diets do not alter the frequency of ulcer recurrence. Although caffeine is a gastric acid stimulant, constituents in decaffeinated coffee or tea, caffeine-free carbonated beverages, beer, and wine may also increase gastric acid secretion. In high concentrations, alcohol ingestion is associated with acute gastric mucosal damage and upper GI bleeding; however, there is insufficient evidence to confirm that alcohol causes ulcers.

**PATHOPHYSIOLOGY**

A physiologic imbalance between aggressive (gastric acid and pepsin) and protective factors (mucosal defense and repair) remain important issues in the pathophysiology of gastric and duodenal ulcers. Gastric acid is secreted by the parietal cells, which contain receptors for histamine, gastrin, and acetylcholine. Acid (as well as *H. pylori* infection and NSAID use) is an independent factor that contributes to the disruption of mucosal integrity. Increased acid secretion has been observed for patients with duodenal ulcers and may be a consequence of *H. pylori* infection. Patients with Zollinger-Ellison syndrome (ZES) (described in the section Zollinger-Ellison Syndrome) have profound gastric acid hypersecretion resulting from a gastrin-producing tumor. In contrast, patients with gastric ulcer usually have normal or reduced rates of acid secretion (hypochlorhydria).

Acid secretion is expressed as the amount of acid secreted under basal or fasting conditions, basal acid output (BAO); after maximal stimulation, maximal acid output (MAO); or in response to a meal. Basal, maximal, and meal-stimulated acid secretion varies according to time of day and the individual’s psychological state, age, gender, and health status. The BAO follows a circadian rhythm, with the highest acid secretion occurring at night and the lowest in the morning. An increase in the BAO:MAO ratio suggests a basal hypersecretory state such as ZES. A review of gastric acid secretion, and its regulation can be found elsewhere.

Pepsin is an important cofactor that plays a role in the proteolytic activity involved in ulcer formation. The inactive precursor of pepsin, secreted by the chief cells located in the gastric fundus (see Fig. 40–1). Pepsin is activated by acid pH (optimal pH of 1.8 to 3.5), inactivated reversibly at pH 4, and irreversibly destroyed at pH 7.

Mucosal defense and repair mechanisms (mucus and bicarbonate secretion, intrinsic epithelial cell defense, and mucosal blood flow) protect the gastroduodenal mucosa from noxious endogenous and exogenous substances. The viscous nature and near-neutral pH of the mucus-bicarbonate barrier protect the stomach from the acidic contents in the gastric lumen. Mucosal repair after injury is related to epithelial cell restitution, growth, and regeneration. The maintenance of mucosal integrity and repair is mediated by the production of endogenous prostaglandins. The term cytoprotection is often used to describe this process, but mucosal defense and mucosal protection are more accurate terms, as prostaglandins prevent deep mucosal injury and not superficial damage to individual cells. Gastric hyperpermeability and increased prostaglandin synthesis characterize adaptive cytoprotection, the short-term adaptation of mucosal cells to mild topical irritants. This phenomenon enables the stomach to initially withstand the damaging effects of irritants. Alterations in mucosal defense that are induced by *H. pylori* or NSAIDs are the most important cofactors in the formation of peptic ulcers.

**HELIcobacter pylori**

*H. pylori* is a spiral-shaped, pH-sensitive, gram-negative, microaerophilic bacterium that resides between the mucus layer and surface epithelial cells in the stomach, or any location where gastric-type epithelium is found. The combination of its spiral shape and flagellum permits it to move from the lumen of the stomach, where the pH is low, to the mucus layer, where the local pH is neutral. *H. pylori* produces large amounts of urease, which hydrolyzes urea in the gastric juice and converts it to ammonia and carbon dioxide. The local buffering effect of ammonia creates a neutral environment within and surrounding the bacterium, which protects it from the lethal effect of gastric acid. *H. pylori* also produces acid-inhibitory proteins, which allows it to adapt to the low-pH environment of the stomach.

*H. pylori* binds to specific regions within the stomach. It attaches to gastric-type epithelium by adherence pedestals, which prevent the organism from being shed during cell turnover and mucous secretion. Colonization of the antrum and corpus (body) of the stomach is associated with gastric ulcer and cancer. Antinuclear factors colonize gastric metaplastic tissue (gastric tissue that develops in the duodenum secondary to changes in gastric acid or bicarbonate secretion) leading to duodenal ulcer (see Fig. 40–2). Although *H. pylori* causes chronic gastric mucosal inflammation in all infected
individuals, only a minority actually develop an ulcer or gastric cancer.\textsuperscript{1,2,3} The difference in the diverse clinical outcomes is related to variations in bacterial pathogenicity and host susceptibility.\textsuperscript{2,22}

Mucosal injury is produced by (1) elaborating bacterial enzymes (urease, lipases, and proteases), (2) adherence, and (3) \textit{H. pylori} virulence factors.\textsuperscript{2,22} Lipases and proteases degrade gastric mucus, ammonia produced by urease may be toxic to gastric epithelial cells, and bacterial adherence enhances the uptake of toxins into gastric epithelial cells. \textit{H. pylori} induces gastric inflammation by altering the host inflammatory response and damaging epithelial cells directly by cell-mediated immune mechanisms or indirectly by activated neutrophils or macrophages attempting to phagocytose bacteria or bacterial products.\textsuperscript{2,22} However, \textit{H. pylori} strains are genetically diverse and account for differences in adaptation within the human host. Two of the most important are cytotoxin-associated gene protein (CagA) and vacuolating cytotoxin (VacA). About 60\% of \textit{H. pylori} strains in the United States possess CagA, but CagA-positive strains increase the risk for severe PUD, gastritis, and gastric cancer compared with CagA-negative strains.\textsuperscript{2,22} The VacA gene codes for the Vac-A cytotoxin, a vacuolizing toxin. Although VacA is present in most all \textit{H. pylori} strains, strains vary in cytotoxicity and increased risk for peptic ulcer and gastric cancer.\textsuperscript{2,22} Host polymorphisms are important markers of disease susceptibility and may identify high-risk patients.\textsuperscript{2,29} Polymorphisms of interleukin (IL)-1\textbeta and its receptor antagonist, as well as tumor necrosis factor \textalpha (TNF-\textalpha) and IL-10, may be associated with increased gastric acid secretion and duodenal ulcer or acid suppression and gastric cancer.\textsuperscript{2,22}

### NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs, including aspirin (see Table 40–3), cause gastric mucosal damage by two important mechanisms: (1) direct or topical irritation of the gastric epithelium and (2) systemic inhibition of endogenous mucosal prostaglandin synthesis.\textsuperscript{1,13} Although the initial injury is initiated topically by the acidic properties of many of the NSAIDs, systemic inhibition of the protective prostaglandins limits the ability of the mucosa to defend itself against injury and thus plays the predominant role in the development of gastric ulcer.\textsuperscript{1,13}

Topical irritant properties are predominantly associated with acidic NSAIDs (e.g., aspirin) and their ability to decrease the hydrophobicity of the mucous gel layer in the gastric mucosa. Most nonaspirin NSAIDs have topical irritant effects, but aspirin is the most damaging. Although NSAID prodrugs, enteric-coated aspirin tablets, salicylate derivatives, and parenteral or rectal preparations are associated with less-acute topical gastric mucosal injury, they can cause ulcers and related GI complications as a result of their systemic inhibition of endogenous PGs.\textsuperscript{7}

Cyclooxygenase (COX) is the rate-limiting enzyme in the conversion of arachidonic acid to prostaglandins and is inhibited by NSAIDs (Fig. 40–3). Two similar COX isoforms have been identified: cyclooxygenase-1 (COX-1) is found in most body tissue, including the stomach, kidney, intestine, and platelets; cyclooxygenase-2 (COX-2) is undetectable in most tissues under normal physiologic conditions, but its expression can be induced during acute inflammation and arthritis (Fig. 40–4).\textsuperscript{1,13} COX-1 produces protective prostaglandins that regulate physiologic processes such as GI mucosal integrity, platelet homeostasis, and renal function. COX-2 is induced (unregulated) by inflammatory stimuli such as cytokines and produces prostaglandins involved with inflammation, fever, and pain. COX-2 is also constitutionally expressed in organs such as the brain, kidney, and reproductive tract. Adverse effects (e.g., GI or renal toxicity) of NSAIDs are primarily associated with the inhibition of COX-1, whereas antiinflammatory actions result primarily from NSAID inhibition of COX-2.\textsuperscript{1,13}

Figure 40-3. Metabolism of arachidonic acid after its release from membrane phospholipids. Broken arrow indicates inhibitory effects. (ASA, aspirin; HPETE, hydroperoxyeicosatetraenoic acid; NSAIDs, nonsteroidal antiinflammatory drugs; PG, prostaglandin.)

The COX-1-to-COX-2 inhibitory ratio determines the relative GI toxicity of a specific NSAID. Nonselective NSAIDs, including aspirin, inhibit both COX-1 and COX-2 to varying degrees and are associated with an increased propensity to cause gastric ulcers.\textsuperscript{1,13} In contrast, the selective COX-2 inhibitors are associated with a reduction in ulcers and related GI complications, but the benefit of celecoxib, is less that that of rofecoxib and valdecoxib (see Table 40–3). The addition of aspirin to a selective COX-2 inhibitor reduces its ulcer-sparing benefit and increases ulcer risk.\textsuperscript{1,13} Aspirin and nonaspirin NSAIDs irreversibly inhibit platelet COX-1, resulting in decreased platelet aggregation and prolonged bleeding times, thereby increasing the potential for upper and lower GI bleeding.\textsuperscript{1,13,15} Coadministration of selected NSAIDs may reduce the antiplatelet effects of aspirin.\textsuperscript{13,15} Clopidogrel and other medications that impair angiogenesis do not cause ulcers, per se, but may impair healing of gastric erosions leading to ulceration.\textsuperscript{13,15}

### COMPLICATIONS

Upper GI bleeding, perforation, and obstruction occur with \textit{H. pylori}-associated and NSAID-induced ulcers and constitute the most serious, life-threatening complication of chronic PUD.\textsuperscript{1,23} Bleeding is caused by the erosion of an ulcer into an artery. It may be occult (hidden) and insidious or may present as melena.

Figure 40-4. Tissue distribution and actions of cyclooxygenase (COX) isoenzymes. Nonselective nonsteroidal antiinflammatory drugs (NSAIDs) including aspirin (ASA) inhibit COX-1 and COX-2 to varying degrees; COX-2 inhibitors inhibit only COX-2. Broken arrow indicates inhibitory effects.
Clinical Presentation of Peptic Ulcer Disease

The clinical presentation of PUD varies depending on the severity of epigastric pain and the presence of complications (Table 40–5). Ulcer-related pain in duodenal ulcer often occurs 1 to 3 hours after meals and is usually relieved by food, but this is variable. In gastric ulcer, food may precipitate or accentuate ulcer pain. Antacids usually provide immediate pain relief in most ulcer patients. Pain usually diminishes or disappears during treatment; however, recurrence of epigastric pain after healing often suggests an unhealed or recurrent ulcer.

The presence or absence of epigastric pain does not define an ulcer. Ulcer healing does not necessarily render the patient asymptomatic. Why symptoms remain is unclear, but it may relate to sensitization of afferent nerves in response to mucosal injury. Conversely, the absence of pain does not preclude an ulcer diagnosis especially in the elderly who may present with a “silent” ulcer complication. The reasons for this are unclear, but may relate to differences in the way the elderly perceive pain or the analgesic effect of NSAIDs.

Dyspepsia in itself is of little clinical value when assessing subsets of patients who are most likely to have an ulcer. Patients taking NSAIDs often report dyspepsia, but dyspeptic symptoms do not directly correlate with an ulcer. Individuals with dyspeptic symptoms may have either uninvestigated (no upper endoscopy) or investigated (underwent upper endoscopy) dyspepsia. If an ulcer is not confirmed in a patient with ulcer-like symptoms at the time of endoscopy, the disorder is referred to as nonulcer dyspepsia. Ulcer-like symptoms may occur in the absence of peptic ulceration in association with H. pylori gastritis or duodenitis. There is no one sign or symptom that differentiates between H. pylori–positive and NSAID-induced ulcer.

### DIAGNOSIS

Routine laboratory tests are not helpful in establishing the diagnosis of PUD (see Table 40–5).

### SIGNS AND SYMPTOMS

The clinical presentation of PUD varies depending on the severity of epigastric pain and the presence of complications (Table 40–5). Ulcer-related perforation into the peritoneal cavity is generally considered a surgical emergency. About one third to one half of perforated ulcers are associated with the use of NSAIDs, with the highest mortality reported in the elderly. The pain of perforation is usually sudden, sharp, and severe, beginning first in the epigastrium, but quickly spreading over the entire abdomen. Most patients experience ulcer symptoms prior to perforation. However, older patients who experience perforation in association with NSAID use may be asymptomatic. Penetration occurs when an ulcer burrows into an adjacent structure (pancreas, biliary tract, or liver) rather than opening freely into a cavity.

Gastric outlet obstruction is related to mechanical obstruction caused by scarring, muscular spasm or edema of the duodenal bulb usually resulting from chronic ulceration. Symptoms occur over several months and include early satiety, bloating, anorexia, nausea, vomiting, and weight loss. Perforation, penetration, and gastric outlet obstruction occur most often with long-standing PUD.

Treatment of PUD has improved so that even the most virulent ulcers can be managed with medication. Intractability to drug therapy is an infrequent manifestation of PUD and an infrequent indication for surgery.

### TESTS FOR HELICOBACTER PYLORI

The diagnosis of H. pylori infection can be made using endoscopic or nonendoscopic tests (Table 40–6). The tests that require upper endoscopy are invasive, more expensive, and usually require a mucosal biopsy for histology, culture, or detection of urease activity. At least three tissue samples are taken from specific areas of the stomach, as patchy distribution of H. pylori infection can lead to false-negative results. Because certain medications may decrease the sensitivity of rapid urease test, antibiotics and bismuth salts should be withheld for 4 weeks and proton pump inhibitors (PPIs) for 1 to 2 weeks prior to endoscopic testing. If the patient has been taking these medications, then a gastric biopsy for histology should be performed.

Two types of nonendoscopic tests are available: tests that identify active infection and tests that detect antibodies (see Table 40–6). Antibody tests do not differentiate between active infection and previously eradicated H. pylori. The nonendoscopic tests include the urea breath test (UBT), serologic antibody detection tests, and the fecal antigen test. These tests are less invasive, more convenient, and less expensive than the endoscopic tests.

The UBT is the most accurate noninvasive test and is based on H. pylori urease activity. The ¹³carbon (nonradioactive isotope) and ¹⁴carbon (radioactive isotope) tests require that the patient ingest radiolabeled urea, which is then hydrolyzed by H. pylori (if present in the stomach) to ammonia and radiolabeled bicarbonate. The radiolabeled bicarbonate is absorbed in the blood and excreted in the breath. A mass spectrometer is used to detect ¹³Carbon whereas ¹⁴Carbon is measured using a scintillation counter. The fecal antigen test is less expensive and easier to perform than the UBT, and may...
be useful in children. Although comparable to the UBT in the initial detection of \emph{H. pylori}, the fecal antigen test is less accurate when used to confirm \emph{H. pylori} eradication posttreatment and is considered an alternative to the UBT.

Serologic tests are a cost-effective alternative for the initial diagnosis of \emph{H. pylori} infection in the untreated patient.\textsuperscript{3,5} Antibodies to \emph{H. pylori} usually develop about 3 weeks after infection and remain present after successful eradication.\textsuperscript{4} Therefore, serology should not be used to confirm \emph{H. pylori} eradication.\textsuperscript{2,6} Office-based tests are less expensive, widely available and provide rapid results, but the results are less accurate and more variable than the laboratory-based tests. Salivary and urine antibody tests are under investigation.\textsuperscript{5}

Testing for \emph{H. pylori} is only recommended if eradication is planned. Serologic antibody testing is a reasonable choice if endoscopy is not planned. The diagnostic accuracy of \emph{H. pylori} tests for patients with an active bleeding ulcer has been questioned because of the potential for false-negative results. However, endoscopic biopsy-based tests such as the rapid urease test have a high degree of specificity in these patients (see Peptic Ulcer-Related Bleeding).\textsuperscript{2}

Confirmation of eradication is indicated posttreatment of active ulcers, previous ulcers, MALT lymphoma, endoscopic resection of gastric cancer, and uninvestigated dyspepsia, but routine testing in patients is neither cost-effective nor practical.\textsuperscript{3} The decision to test posttreatment should be patient specific and take into consideration the patient's diagnosis, age, and ulcer history. The UBT is the preferred nonendoscopic test to confirm \emph{H. pylori} eradication but must be delayed at least 4 weeks after the completion of treatment to avoid confusing bacterial suppression with eradication. The term \emph{eradication} or \emph{cure} is used when posttreatment tests conducted 4 weeks after the end of treatment do not detect the organism. Quantitative antibody tests are impractical for posttreatment as antibody titers remain elevated for long periods of time. A negative posttreatment antibody test, however, is considered reliable.

### IMAGING AND ENDOSCOPY

The diagnosis of PUD depends on visualizing the ulcer crater either by upper GI radiography or upper endoscopy (see Table 40–5).\textsuperscript{1} In the past, radiography was the initial diagnostic procedure of choice because of its lower cost, greater availability, and greater safety. Today, upper endoscopy has replaced radiography because it provides a more accurate diagnosis and permits direct visualization of the ulcer.

### CLINICAL COURSE AND PROGNOSIS

The natural history of PUD is characterized by periods of exacerbations and remissions.\textsuperscript{2} Ulcer pain is usually recognizable and episodic, but symptoms are variable, especially in older adults and for patients taking NSAIDs. Antiulcer medications, including the histamine-2 receptor antagonists (H\textsubscript{2}RAs), PPIs, and sucralfate, relieve symptoms, accelerate ulcer healing, and reduce the risk of ulcer recurrence, but they do not cure the disease. Both duodenal and gastric ulcers recur unless the underlying cause (\emph{H. pylori} or NSAID) is removed. Successful \emph{H. pylori} eradication markedly decreases ulcer recurrence and complications. Prophylactic cotherapy or a COX-2 inhibitor decreases the risk of upper GI events for patients who are taking NSAIDs. GI bleeding, perforation, or obstruction remain troublesome complications of chronic PUD. Mortality for patients with gastric ulcer is slightly higher than in duodenal ulcer and the general population. The development of gastric cancer in \emph{H. pylori}-infected individuals is a slow process that occurs over 20 to 40 years and is associated with a lifetime risk of less than 1\%.\textsuperscript{2,8}
The eradication of *H. pylori* infection with antimicrobials such as clarithromycin, metronidazole, amoxicillin, bismuth salts, and anti-secretory drugs (PPIs or H2RAs) relieve ulcer symptoms, heal the ulcer, and eradicate *H. pylori* infection. PPIs are preferred to H2RAs or sucralfate for healing *H. pylori*-negative NSAID-induced ulcers because they accelerate ulcer healing and provide more effective relief of symptoms. Treatment with a PPI should be extended to 8 to 12 weeks if the NSAID must be continued. A PPI-based *H. pylori* eradication regimen is recommended when the patient with an active ulcer is taking an NSAID and is *H. pylori*-positive. Prophylactic cotherapy with either a PPI or misoprostol decreases ulcer risk and upper GI complications for patients taking nonselective NSAIDs. Selective COX-2 inhibitor NSAIDs (if available) may be used as an alternative to a nonselective NSAID, but their beneficial GI effect when taken with low-dose aspirin is negated and their association with adverse cardiovascular effects reduce their usefulness.

Dietary modifications are important for patients who are unable to tolerate certain foods and beverages. Lifestyle modifications such as...

---

**FIGURE 40-5.** Algorithm. Guidelines for the evaluation and management of a patient who presents with dyspeptic or ulcer-like symptoms. (COX-2, cyclooxygenase-2; GERD, gastroesophageal reflux disease; *H. pylori*, Helicobacter pylori; H2, H2-receptor antagonist; PPI, proton pump inhibitor; NSAID, nonsteroidal antiinflammatory drug; NUD, nonulcer dyspepsia.)
reducing stress and stopping cigarette smoking is encouraged. Surgery may be necessary for patients with ulcer-related complications.

**NONPHARMACOLOGIC THERAPY**

Patients with PUD should eliminate or reduce psychological stress, cigarette smoking, and the use of NSAIDs (including aspirin). Although there is no “antiulcer diet,” the patient should avoid foods and beverages (e.g., spicy foods, caffeine, and alcohol) that cause dyspepsia or that exacerbate ulcer symptoms. If possible, alternative agents such as acetaminophen or nonacetylated salicylate (e.g., salsalate) should be used for relief of pain. Elective surgery for PUD is rarely performed today because of highly effective medical management. A subset of patients, however, may require emergency surgery for bleeding, perforation, or obstruction. In the past, surgical procedures were performed for medical treatment failures and included vagotomy with pyloroplasty or vagotomy with antrectomy. Vagotomy (truncal, selective, or parietal cell) inhibits vagal stimulation of gastric acid. A truncal or selective vagotomy frequently results in postoperative gastric dysfunction and requires a pyloroplasty or antrectomy to facilitate gastric drainage. When an antrectomy is performed, the remaining stomach is anastomosed with the duodenum (Billroth I) or with the jejunum (Billroth II). A vagotomy is unnecessary when an antrectomy is performed for gastric ulcer. Postoperative consequences include postvagotomy diarrhea, dumping syndrome, anemia, and recurrent ulceration.

**PHARMACOLOGIC THERAPY**

Recommendations

Table 40–7 presents guidelines for the eradication of infection in *H. pylori*-positive individuals. Table 40–8 lists regimens used to eradicate *H. pylori* infection.

First-line therapy is usually initiated with a PPI-based triple-drug regimen for 10 to 14 days. If a second course of treatment is required, the PPI-based three-drug regimen should contain different antibiotics or a four-drug regimen with a bismuth salt, metronidazole, tetracycline, and a PPI should be used.

### TABLE 40-7 Guidelines for the Eradication of Helicobacter pylori Infection

<table>
<thead>
<tr>
<th>Indications for treatment of <em>H. pylori</em> infection</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Established indications for the treatment of <em>H. pylori</em> include gastric or duodenal ulcer, mucosa-associated lymphoid tissue (MALT) lymphoma, after endoscopic resection of gastric cancer, and uninvestigated dyspepsia.</td>
</tr>
<tr>
<td>• Controversial indications for the treatment of <em>H. pylori</em> infection include nonulcer dyspepsia, gastroesophageal reflux disease, individuals taking nonsteroidal antiinflammatory drugs (NSAIDs), individuals at high risk for gastric cancer, and unexplained iron deficiency anemia.</td>
</tr>
</tbody>
</table>

**Initial treatment of *H. pylori* infection**

• Use only those eradication regimens that are of proven effectiveness in the United States.

• In the United States, first-line treatment should include a proton pump inhibitor (PPI), clarithromycin, and either amoxicillin or metronidazole (PPI-based triple therapy) for 10–14 days.

• The PPI-based triple therapy amoxicillin-containing regimen is preferred initially because bacterial resistance to amoxicillin is almost absent, it has fewer adverse effects, and it leaves metronidazole as a backup agent for second-line therapy.

• In penicillin allergic patients, metronidazole should be substituted for amoxicillin in the PPI-based triple therapy regimen and yields similar results when combined with clarithromycin.

• An alternate initial strategy includes a PPI or H₂RA, bismuth salt, tetracycline, and metronidazole (bismuth-based quadruple therapy) for 10–14 days.

• Sequential therapy consisting of a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and metronidazole for 5 days is an alternative to PPI-based triple therapy or PPI-based quadruple therapy, but requires further validation before it can be recommended as first-line therapy in the United States.

**Eradication of *H. pylori* after initial treatment failure**

• Avoid antibiotics that have been used in previous eradication regimens.

• Bismuth-based quadruple therapy with a bismuth salt, tetracycline, metronidazole, and a PPI or H₂RA for 10–14 days is an acceptable treatment regimen for persistent *H. pylori* infections.

• PPI-based triple therapy with levofloxacin and amoxicillin for 10 days may be more effective and better tolerated than PPI-based quadruple therapy with a bismuth salt, tetracycline, and metronidazole, but it requires further validation in the United States.

<sup>a</sup>Although treatment is minimally effective if used for 7 days, 10–14 days is recommended. The antisecretory drug may be continued beyond antimicrobial treatment for patients with a history of a complicated ulcer, e.g., bleeding, or in heavy smokers.

<sup>b</sup>Standard PPI peptic ulcer healing dosages given once or twice daily (see Table 40–9).

<sup>c</sup>Standard H₂RA peptic ulcer healing dosages may be used in place of a PPI (see Table 40–9).

<sup>d</sup>Bismuth subcitrate potassium (bismuthcitrate) 140 mg, as the bismuth salt, is contained in a prepackaged capsule (Pylera), along with metronidazole 125 mg and tetracycline 125 mg; three capsules are taken with each meal and at bedtime; a standard PPI dosage is added to the regimen and taken twice daily. All medications are taken for 10 days.

<sup>e</sup>Requires validation as first-line therapy in the United States.

<sup>f</sup>Requires validation as rescue therapy in the United States.

*RA, H₂-receptor antagonist; PPI, proton pump inhibitor.

Data from references 5, 25 to 29.
Patients with NSAID-induced ulcers should be tested to determine their *H. pylori* status. If *H. pylori*–positive, treatment should be initiated with a PPI-based three-drug regimen. If *H. pylori*–negative, the NSAID should be discontinued, and the patient treated with either a PPI, H$_2$RA, or sucralfate (see Table 40–9). If the NSAID is continued, treatment should be initiated with a PPI (if *H. pylori* negative) or with a PPI-based three-drug regimen (if *H. pylori* positive). Cotherapy with a PPI or misoprostol or switching to a selective COX-2 inhibitor (if available) is recommended for patients at risk of developing an ulcer-related complication (see Table 40–10).

Maintenance therapy with a PPI or H$_2$RA should be limited to high-risk patients with ulcer complications, patients who fail eradication, and those with *H. pylori*–negative ulcers. Treatment failure is associated with poor medication adherence, antimicrobial resistance, NSAID use, cigarette smoking, acid hypersecretion, or tolerance to the antisecretory effects of an H$_2$RA.

### Treatment of *Helicobacter Pylori*–Positive Ulcers

This chapter focuses on the eradication of *H. pylori* in adults. A discussion of the treatment of *H. pylori* infection in children is found elsewhere. The treatment of *H. pylori*–positive PUD should be effective, well tolerated, easy to adhere to, and cost-effective. Historically, none of these factors have been addressed in a systematic way making it difficult to identify the best evidence-based treatment regimens. Successful eradication depends on the drug regimen, resistance to the antibiotics used, duration of therapy, medication adherence, and genetic polymorphism. *H. pylori* regimens should have eradication (cure) rates of at least 80% based on intention-to-treat analysis or at least 90% based on per-protocol analysis, and they should minimize the potential for antimicrobial resistance. Not one antibiotic, bismuth salt, or antacids can achieve this goal, but clarithromycin is the single most effective antibiotic. Two-drug regimens that combine a PPI and either amoxicillin or clarithromycin have yielded marginal and variable eradication rates in the United States and are not recommended. In addition, the use of only one antibiotic is associated with a higher rate of antimicrobial resistance.

Drug regimens (see Table 40–8) that combine an antisecretory drug with two antibiotics (triple therapy) or with two antibiotics and a bismuth salt (quadruple therapy) usually increase eradication rates to acceptable levels and reduce the risk of antimicrobial resistance. When selecting an initial eradication regimen, an antibiotic combination should be used that permits second-line treatment (if necessary) with different antibiotics. The antibiotics that have been most extensively studied and found to be effective in various combinations include clarithromycin, amoxicillin, metronidazole, and tetracycline. Because of insufficient data, ampicillin should not be substituted for amoxicillin, doxycycline should not be substituted for tetracycline,

and azithromycin or erythromycin should not be substituted for clarithromycin. Antisecretory drugs enhance antibiotic activity and stability by increasing intragastric pH and by decreasing intragastric volume thereby enhancing the topical antibiotic concentration.27

### Proton Pump Inhibitor-Based Three-Drug Regimens

PPI-based triple therapy (see Table 40–8) is the initial treatment of choice for eradicating H. pylori (see Table 40–7).3,25–29 The regimens that combine either clarithromycin and amoxicillin or clarithromycin and metronidazole are more effective than the amoxicillin–metronidazole regimen. In most cases, increasing the antibiotic dosage does not improve eradication rates. The clarithromycin–amoxicillin regimen is preferred initially (see Table 40–7), but metronidazole should be substituted for amoxicillin for penicillin-allergic patients unless alcohol is consumed.2,25–27 Unfortunately, eradication rates for PPI-based triple therapy have declined substantially in recent years in North America and Europe due primarily to an increase in clarithromycin-resistant H. pylori strains (see the section Factors that Contribute to Unsuccessful Eradication).5,25–27 Other antibiotics and antibiotic combinations have been investigated, but these regimens should not be used as initial treatment in the United States until well-designed trials confirm their effectiveness.5,27

The recommended duration of therapy in the United States is 10 to 14 days, but the 14-day regimen is preferred in light of the decreasing eradication rate with the PPI-based triple therapy regimens containing clarithromycin.5 Although a 7-day course has been approved by the FDA and is in use in Europe, the longer treatment periods favor higher eradication rates and are less likely to be associated with antimicrobial resistance.5,21–27

#### CLINICAL CONTROVERSY

Some clinicians favor an initial 7-day H. pylori regimen even though clinical guidelines suggest a longer treatment course. These clinicians believe that the shorter treatment period enhances the compliance of a complicated drug regimen. Others adhere to clinical guidelines and recommend a 10- or 14-day treatment period that favors higher eradication rates in the compliant patient and is less likely to contribute to antimicrobial resistance.

The PPI is an integral part of the three-drug regimen and should be taken 30 to 60 minutes before a meal along with the two antibiotics (see Table 40–8).3,25 Prolonged PPI treatment beyond 2 weeks after eradication is usually not necessary for ulcer healing. A single daily dose of a PPI may be less effective than a twice daily dose.39 Substitution of one PPI for another is acceptable and does not enhance or diminish H. pylori eradication.32,34 An H2 RA should not be substituted for a PPI, as H2 RA is associated with lower eradication rates.35,36 Pretreatment with a PPI does not influence H. pylori eradication.37

#### Bismuth-Based Four-Drug Regimens

Bismuth-based quadruple therapy (see Table 40–8) is recommended as an alternative first-line eradication therapy (see Table 40–7) for those allergic to penicillin.5,21–29 Although this regimen may be used initially, it is often reserved as a second-line therapy after treatment failure with the PPI-based clarithromycin-amoxicillin regimen (see the section Eradication of H. Pylori After Initial Treatment Failure). Eradication rates for bismuth-based quadruple therapy (bismuth salicylate, metronidazole, tetracycline, and either a PPI or H2 RA) are similar to those achieved with PPI-based triple therapy.5,27,38

Eradication rates are comparable when bismuth subcitrate potassium (biskalcitrate) is substituted for bismuth subsalicylate (see Table 40–8).39 Substitution of amoxicillin for tetracycline lowers the eradication rate and is usually not recommended.39 Substitution of clarithromycin 250 to 500 mg four times a day for tetracycline yields similar results but increases adverse effects. Bismuth salts have a topical antimicrobial effect.1 The antisecretory drug hastens ulcer healing and relieves pain in patients with an active ulcer. All medications except the PPI should be taken with meals and at bedtime.

The original bismuth-based regimens contained an H2 RA in place of a PPI, but a recent metaanalysis indicated that quadruple therapy with a PPI provides greater efficacy and permits a shorter treatment duration (7 days) when compared with the H2 RA-based regimens (10 to 14 days).40 However, a 10- to 14-day duration is recommended in the United States as it generally provides higher eradication rates.3 When treating an active ulcer, the antisecretory drug is usually continued for 2 (PPI) to 4 (H2 RA) weeks after stopping bismuth and antibiotics. Bismuth-based quadruple therapy is the treatment of choice when medication costs are of overriding importance. However, major concerns include a 4-time-a-day dosing regimen (see Table 40–8), poor medication adherence, and frequent adverse effects. Although minor adverse effects are more common, the frequency of moderate or severe adverse effects is similar to those reported for the PPI-based triple therapy.41

#### Sequential Therapy

Sequential therapy is a new form of eradication therapy whereby the antibiotics are administered in a sequence rather than all together.5,26,27 The rationale for sequential therapy is to initially treat with antibiotics that rarely promote resistance (e.g., amoxicillin) to reduce the bacterial load and preexisting resistant organisms and then to follow with different antibiotics (e.g., clarithromycin and metronidazole) to kill the remaining organisms.1 Treatment consists of a PPI and amoxicillin for 5 days followed by a PPI, clarithromycin, and metronidazole for an additional 5 days (see Table 40–8).3,26,42 Although this regimen has achieved eradication rates that are superior to the PPI-based three-drug regimens containing clarithromycin,5 the regimen requires a change in medication mid-treatment, which may contribute to nonadherence.43 The advantages of sequential therapy need to be confirmed in the United States before it can be recommended as a first-line H. pylori eradication therapy (see Table 40–7).5,26,27

#### Eradication of H. Pylori After Initial Treatment Failure

H. pylori eradication is often more difficult after initial treatment fails and successful eradication after retreatment is extremely variable.34 Treatment failures should be referred to a gastroenterologist for further diagnostic evaluation. Second-line (salvage) treatment should (a) use antibiotics that were not previously used during initial therapy; (b) use antibiotics that are not associated with resistance; (c) use a drug that has a topical effect such as bismuth; and (d) extend the duration of treatment to 14 days.3,22,44 The most commonly used second-line therapy, after unsuccessful initial treatment with a PPI-amoxicillin-clarithromycin regimen, is a 14-day course of the PPI-based quadruple therapy (see Table 40–8).3,26,27,45 A levofloxacin-containing regimen (see Table 40–8) may be an alternative second-line eradication regimen and may be better tolerated than PPI-based quadruple therapy (see Table 40–7).46 Additionally, the levofoxacin regimen may serve as an alternative to PPI-clarithromycin-metronidazole usually recommended in penicillin-allergic patients.47 However, concerns about using fluoroquinolones for H. pylori eradication are related to the development of resistance and adverse effects such as tendinitis and hepatotoxicity.26 Other second-line regimens which include rifabutin and furazolidone are discussed elsewhere.5,25–27
Factors That Predict \textit{H. Pylori} Eradication Outcomes

Factors that predict \textit{H. pylori} eradication outcomes include antibiotic resistance, poor medication adherence, short duration of therapy, CagA status, high bacterial load, low intra gastric pH, and genetic polymorphism.\textsuperscript{4,5,6,7} Medication adherence decreases with multiple medications, increased frequency of administration, intolerable adverse effects, and costly drug regimens. One metaanalysis reported that CYP2C19 polymorphism may alter the effect of PPIs on gastric acid secretion thereby influencing eradication outcomes.\textsuperscript{5,6} Tolerance varies with different regimens.\textsuperscript{1,3} Common adverse effects include nausea, vomiting, abdominal pain, diarrhea and taste disturbances (metronidazole and clarithromycin). Adverse effects with metronidazole are dose-related (especially when >1 g/day) and include a disulfiram-like reaction with alcohol. Tetracycline may cause photosensitivity and should not be used in children because of possible tooth discoloration. Bismuth salts may cause darkening of the stool and tongue. Antibiotic-associated colitis occurs occasionally. Oral thrush and vaginal candidiasis may also occur.

An important predictor of \textit{H. pylori} eradication is the presence or absence of resistant microorganisms.\textsuperscript{5,6,9} United States data from 1993 to 1999 report resistance rates among \textit{H. pylori} strains for metronidazole (37%), clarithromycin (10%), and amoxicillin (1.4%).\textsuperscript{31} Data from 1998 to 2002 reveal rates of 25% for metronidazole, 13% for clarithromycin, and 0.9% for amoxicillin.\textsuperscript{28} It is possible that the increased rate of clarithromycin resistance partially explains the decrease in efficacy of clarithromycin-containing regimens. The clinical importance of metronidazole resistance remains uncertain, as resistance can be overcome by using higher dosages and combining metronidazole with other antibiotics.\textsuperscript{5} Resistance to tetracycline and amoxicillin is uncommon.\textsuperscript{9} Resistance to bismuth has not been reported. The role of antibiotic sensitivity testing prior to initiating \textit{H. pylori} treatment has not been established.

Probiotics

Probiotics (e.g., strains of \textit{Lactobacillus} and \textit{Bifidobacterium}) and foodstuffs (e.g., cranberry juice and some milk proteins) with bioactive components have been used proactively to control \textit{H. pylori} colonization in at-risk individuals and, when taken as a supplement to eradication therapy, may have a role in improving \textit{H. pylori} eradication and reducing the adverse effects of PPI-based triple therapy.\textsuperscript{25} However, the administration of probiotics alone does not eradicate \textit{H. pylori} infection. In the future, the regular intake of probiotics may constitute a low-cost alternative for individuals who are at-risk for \textit{H. pylori} infection and, in combination with antibiotics, augment eradication rates. These preliminary data are encouraging and warrants more research in this area.

Treatment of NSAID-Induced Ulcers

Nonselective NSAIDs should be discontinued (when possible) upon confirmation of an active ulcer. If the NSAID is stopped, most uncomplicated ulcers heal with standard regimens of an H\textsubscript{2}RA, PPI, or sucralfate (see Table 40–9).\textsuperscript{1,3} However, the PPIs are usually preferred because they provide more rapid symptom relief and ulcer healing. If the NSAID is continued despite ulceration, consideration should be given to reducing the NSAID dose, switching to acetylsalicylic acid or a nonacetylated salicylate or to using a more selective COX-2 inhibitor (see Table 40–3). The PPIs are the drugs of choice when the NSAID is continued, as potent acid suppression is required to accelerate ulcer healing.\textsuperscript{1,3,9} If the ulcer is \textit{H. pylori}-positive, eradication should be initiated with a regimen that contains a PPI.\textsuperscript{1,3,9}

Strategies to Reduce the Risk of NSAID Ulcer and GI Complications

There are three therapeutic approaches to reducing the risk of NSAID ulcers and related GI complications (see Table 40–10). Medical cotherapy with either a PPI or misoprostol decreases ulcer risk and GI complications in high-risk patients.\textsuperscript{12–14,16,19,29} The use of a selective COX-2 inhibitor instead of a nonselective NSAID also decreases risk of ulcers and upper GI events.\textsuperscript{12,14,16,18,19,29} Unfortunately, these strategies do not completely eliminate ulcers and complications for patients at the “highest risk.” When selecting a gastroprotective strategy, the GI benefits must be balanced against the cardiovascular risks associated with selective COX-2 inhibitor NSAIDs, nonselective NSAIDs, and concomitant antplatelet therapy.\textsuperscript{12–14} Strategies aimed at reducing the topical irritant effects of nonselective NSAIDs, e.g., formulae, slow-release formulations, and enteric-coated products, do not prevent ulcers or GI complications.

Misoprostol Cotherapy

Misoprostol, 200 mcg orally 4 times per day, reduces the risk of NSAID-induced gastric and duodenal ulcer, and related upper GI complications, but diarrhea and abdominal cramping limit its use.\textsuperscript{12,16,56} Because a dosage of 200 mcg 3 times per day is comparable in efficacy to 800 mcg/day, the lower dosage should be considered for patients unable to tolerate the higher dose.\textsuperscript{12} Reducing the misoprostol dosage to 400 mcg per day or less to minimize diarrhea compromises its gastroprotective effects. A fixed combination of misoprostol 200 mcg and diclofenac (50 mg or 75 mg) may enhance compliance, but the flexibility to individualize drug dosage is lost. A large clinical trial in rheumatoid arthritis patients provided the most compelling evidence that misoprostol reduces the risk of upper GI complications for high-risk patients.\textsuperscript{37}

Proton Pump Inhibitor Cotherapy

PPI cotherapy reduces NSAID-related gastric and duodenal ulcer risk and is better tolerated than misoprostol.\textsuperscript{12,14,16,56} All PPIs are effective when used in standard dosages (see Table 40–9). Although head-to-head comparative trials are few, there are limited data to indicate that PPIs are superior to standard H\textsubscript{2}RA dosages.\textsuperscript{12,13,14} When lansoprazole (15 or 30 mg/day) was compared with misoprostol 800 mcg/day or placebo, both dosages of lansoprazole and misoprostol effectively reduced ulcer recurrence, although the PPI was better tolerated.\textsuperscript{58} A greater proportion of those in the misoprostol group reported treatment-related adverse events and withdrew early from the study. Results from observational studies and metaanalyses indicate the PPIs reduce the risk of NSAID-related ulcer bleeding.\textsuperscript{12,14,19,59}

\textit{H\textsubscript{2}}-Receptor Antagonist Cotherapy

Standard H\textsubscript{2}RA dosages (e.g., famotidine 40 mg/day) are effective in reducing NSAID-related duodenal ulcer but not gastric ulcer (the most frequent type of ulcer associated with NSAIDs).\textsuperscript{12,13,14} Higher dosages (e.g., famotidine 40 mg twice daily, ranitidine 300 mg twice daily) may reduce the risk of gastric and duodenal ulcer, but studies comparing double dosages with PPIs or misoprostol are not available.\textsuperscript{12,13} One study suggests that famotidine 20 mg twice daily may be an alternative to PPIs for patients taking low cardioprotective dosages of aspirin, but additional studies are required to confirm these findings.\textsuperscript{59} The H\textsubscript{2}RAs are not recommended as prophylactic cotherapy because it is likely that they are not as effective as the PPIs or misoprostol in preventing NSAID-induced gastric ulcer and related GI complications.\textsuperscript{59} An H\textsubscript{2}RA, however, may be used to relieve NSAID-related dyspepsia.

Cyclooxygenase-2 Inhibitors

Two large outcome trials have compared celecoxib\textsuperscript{61} and rofecoxib\textsuperscript{62} to nonselective NSAIDs. Patients in the Celecoxib Long-term Arthritis Safety Study (CLASS) trial who were taking celecoxib and required cardioprotection...
(antiplatelet effects of aspirin) were permitted to take low-dose aspirin. Although a 6-month analysis found a nonsignificant reduction in ulcer complications with celecoxib when compared with ibuprofen and diclofenac, results after 1 year found no difference between the groups. Today, celecoxib is not considered a selective COX-2 inhibitor (Table 40–3) by the FDA as it contains the same GI warnings as the nonselective and partially selective NSAIDs. A post hoc analysis confirmed that any gastroprotective benefits of celecoxib were negated in aspirin users. Similar effects have been observed with rofecoxib.

The Vioxx Gastrointestinal Outcomes Research (VIGOR) trial excluded aspirin users and found that ulcers and ulcer-related complications were significantly reduced with rofecoxib when compared with naproxen. However, there was an increased number of nonfatal myocardial infarctions observed in the rofecoxib group compared with those taking naproxen. It was initially suggested that the lack of antiplatelet effects from rofecoxib, in contrast to the platelet inhibition associated with naproxen, was responsible for the increased thrombotic events observed in the rofecoxib group. Rofecoxib was later withdrawn from the market following an interim analysis of a study to prevent colorectal adenomas that revealed an increased risk of myocardial infarction and thrombotic stoke with rofecoxib when compared with placebo. Subsequently, valdecoxib was withdrawn from the market amid concerns about cardiovascular risk.

Cardiovascular safety was also evaluated in the CLASS trial, but serious cardiovascular thromboembolic events were no different between celecoxib and the comparative nonselective NSAIDs. In contrast, the results of a metaanalysis of randomized trials of COX-2 inhibitor NSAIDs reported a dose-dependent increase in cardiovascular events with all COX-2 inhibitor NSAIDs, including celecoxib. Increased cardiovascular risk appears to be dependent on a number of factors including increased COX-2 selectivity, higher dosages, and a longer duration of treatment. Thus, the lowest effective celecoxib dose should be used for the shortest duration of time. Dyspepsia and abdominal pain, fluid retention, hypertension, and renal toxicity are associated with the COX-2 inhibitors and nonselective NSAIDs.

**COX-2 Inhibitor Versus NSAID plus PPI**

There are limited data that suggest that for high-risk, *H. pylori*-negative patients, a COX-2 inhibitor NSAID may be as beneficial as a nonselective NSAID plus a PPI in reducing NSAID-related ulcer complications. However, neither the COX-2 inhibitor NSAID nor the NSAID plus a PPI will eliminate upper GI events for these patients. Combining a COX-2 inhibitor NSAID with a PPI may be considered for very high-risk patients, but this regimen is likely to be of modest benefit.

**Gastrointestinal and Cardiovascular Safety Issues**

There is no difference in cardiovascular risk between the selective COX-2 inhibitor NSAIDs and the nonselective or partially selective NSAIDs, with the exception of naproxen. Thus, individual patient risk factors for NSAID-related GI bleeding and cardiovascular events must be weighed when determining treatment (see Table 40–10). Naproxen is preferred to nonnaproxen NSAIDs and COX-2 inhibitors because of its comparative cardiovascular safety and not because of its GI safety profile. There is insufficient evidence regarding the preferred NSAID for patients also taking low-dose aspirin. 

Clopidogrel should not be substituted for low-dose aspirin in order to reduce recurrent GI bleeding as it is inferior to a PPI plus low-dose aspirin. Despite limited evidence to suggest an interaction via the hepatic cytocrome P450 (CYP450) pathway, combining a PPI and clopidogrel with or without low-dose aspirin results in less GI bleeding. Ongoing studies for patients with cardiovascular disease should provide the necessary information to help resolve these issues. The lowest possible daily dose of a COX-2 inhibitor should be used as the cardiovascular risk may be dose dependent. However, no studies, to date, have evaluated the safety of low-dose COX-2 inhibitor NSAIDs for patients with or at risk for cardiovascular disease. In the future, there will be new formulations and classes of NSAIDs and COX-2 inhibitors with an improved GI and cardiovascular safety profile. Until then patients who take NSAIDs or COX-2 inhibitors should be counseled about the signs and symptoms of upper GI bleeding and major cardiovascular events and what they should do if they occur.

**Treatment of non-*H. pylori*, non-NSAID Ulcers**

Very few individuals have non-*H. pylori*, non-NSAID (idiopathic) ulcers. Patients should be double-checked to verify that they are *H. pylori* negative and that they are not taking ulcerogenic medications. Possible explanations for non-*H. pylori*, non-NSAID ulcers include gastric hypersecretion, gastric outlet obstruction, genetic predisposition, concomitant diseases (see Table 40–2), and heavy tobacco use. Treatment should be initiated with conventional ulcer healing therapy (see Table 40–9). Although standard H 2RA or sulcrate dose regimens heal the majority of gastric and duodenal ulcers in 6 to 8 weeks, PPIs provide comparable ulcer healing rates in 4 weeks. A higher daily dose or a longer treatment duration is sometimes needed to heal larger gastric ulcers. Antacids are not used as single agents to heal ulcers because of the high volume and frequent doses required. When conventional antiulcer therapy is discontinued after ulcer healing, most patients develop a recurrent ulcer within 1 year. Maintenance therapy may be required to prevent ulcer recurrence.

**Long-Term Maintenance of Ulcer Healing**

Continuous antiulcer therapy is aimed at the long-term maintenance of ulcer healing and the prevention of ulcer-related complications. Because *H. pylori* eradication dramatically decreases ulcer recurrence, continuous maintenance therapy is primarily used to treat high-risk patients who failed *H. pylori* eradication, have a history of ulcer-related complications, have frequent recurrences of *H. pylori*-negative ulcers, and are heavy smokers or NSAID users. For most patients, standard maintenance dosages (see Table 40–9) are effective.

**Treatment of Refractory Ulcers**

Ulcers are considered refractory to therapy when symptoms, ulcers, or both persist beyond 8 to 12 weeks despite conventional treatment or when several courses of *H. pylori* eradication fail. Poor patient compliance, antimicrobial resistance, cigarette smoking, NSAID use, gastric acid hypersecretion, or tolerance to the antisecretory effects of an H 2RA (see the section Antiulcer Agents) may contribute to refractory PUD. Patients with refractory ulcers should undergo upper endoscopy to confirm a nonhealing ulcer, exclude malignancy, and assess *H. pylori* status. *H. pylori*-positive patients should receive eradication therapy (see the section Treatment of Helicobacter pylori–Associated Ulcers). In *H. pylori*-negative patients, higher PPI dosages (e.g., omeprazole 40 mg/day) heal the majority of ulcers. Continuous treatment with a PPI is often necessary to maintain healing, as refractory ulcers recur when therapy is discontinued or the dose is reduced. Switching from one PPI to another is not beneficial. Patients with refractory gastric ulcer may require surgery because of the possibility of malignancy.
Antulcer Agents

Proton Pump Inhibitors The PPIs (omeprazole, esomeprazole, lansoprazole, dexlansoprazole, rabeprazole, and pantoprazole) dose-dependently inhibit basal and stimulated gastric acid secretion. When PPI therapy is initiated, the degree of acid suppression increases over the first 3 to 4 days of therapy, as more proton pumps are inhibited. Because PPIs inhibit only those proton pumps that are actively secreting acid, they are most effective when taken 30 to 60 minutes before meals. The duration of acid suppression is a function of binding to the H+/K+-adenosine triphosphatase (ATPase) enzyme and is longer than their elimination half-lives. Symptomatic acid rebound upon withdrawal of a PPI has been reported in healthy volunteers after 8 weeks of treatment.

Various PPI dosage forms and formulations exist and (see Table 40–9) include the delayed-release enteric-coated dosage forms that have pH-sensitive granules contained in gelatin capsules (omeprazole, esomeprazole, pantoprazole, and dexlansoprazole), rapidly disintegrating tablets (lansoprazole), and delayed release enteric-coated tablets (rabeprazole, pantoprazole, and nonprescription omeprazole). The pH-sensitive enteric coating prevents degradation and premature protonation of the drug in stomach acid but dissolves at a higher pH in the duodenum where the drug is absorbed. Dexlansoprazole is formulated with a dual release mechanism that results in inhibition of proton pumps that become activated after initial release of the medication. Omeprazole is also available as an immediate release formulation (oral suspension, oral capsule) containing sodium bicarbonate, which raises intragastric pH and protects omeprazole from acid degradation in the stomach thus permitting rapid absorption from the duodenum. Intravenous products available in the United States include pantoprazole and esomeprazole.

Five of the PPIs provide similar rates of ulcer-healing (dexlansoprazole has not been labeled at this time for these indications), maintenance of ulcer healing, and symptom relief when used in recommended dosages (see Table 40–9). When higher dosages are indicated, the daily dose should be divided in order to obtain better 24-hour control of intragastric pH. A dosage reduction is unnecessary for patients with renal impairment or in older adults but should be considered in severe hepatic disease. The short-term adverse effects of the PPIs are similar to those observed with the H2RAs and include headache, nausea, and abdominal pain. Because the immediate-release formulations contain sodium bicarbonate, they are contraindicated for patients with metabolic alkalosis and hypocalcemia. The sodium should also be taken into consideration for patients who are on sodium-restricted diets, e.g., congestive heart failure.

Drug Interactions All PPIs increase intragastric pH and may alter the bioavailability of orally administered drugs, such as ketoconazole (weak bases) and digoxin, or pH-dependent dosage forms. This interaction is especially important with atazanavir, a protease inhibitor. Concomitant use with a PPI can significantly reduce the oral bioavailability of atazanavir and potentially lead to therapeutic failure and viral resistance in patients infected with HIV. Omeprazole and esomeprazole selectively inhibit the hepatic CYP2C19 pathway and may decrease the elimination of phenytoin, warfarin, diazepam, and carbamazepine. The PPIs may increase the metabolic clearance and decrease the GI absorption of levothyroxine resulting in increased thyroid-stimulating hormone levels and a corresponding increase in the levothyroxine dose. A review of the FDA database for the years 1997 to 2001 reveals that drug interactions with PPIs are rare and usually do not constitute a major clinical risk.

One of the most perplexing potential PPI drug interactions is with the antiplatelet drug clopidogrel. This interaction is especially important given recent consensus guidelines that recommend the use of a PPI for high-risk patients on antiplatelet therapies to prevent ulcers and related GI bleeding. Clopidogrel, a prodrug, is converted to its active form through CYP2C19. PPIs may attenuate the antiplatelet effect of clopidogrel by inhibiting or competing for this metabolic pathway. FDA safety guidelines recommend that the concomitant administration of omeprazole, omeprazole/sodium bicarbonate, or esomeprazole with clopidogrel be avoided because they reduce the effectiveness of clopidogrel.

X, product is available.

<sup>a</sup> Omeprazole is available as delayed-release enteric-coated pellets in a capsule or as immediate-release capsule that contains 20 or 40 mg of omeprazole with 1100 mg sodium bicarbonate (equivalent to 304 mg of sodium). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg capsules should not be substituted for the 40 mg immediate-release omeprazole-bicarbonate capsule.

<sup>b</sup> Omeprazole oral tablets are available as 20 mg delayed-release nonprescription tablets.

<sup>c</sup> Omeprazole oral suspension is available as 20 or 40 mg omeprazole with 1680 mg sodium bicarbonate (equivalent to 460 mg of sodium). Because 20 and 40 mg dosages contain the same amount of bicarbonate, two 20 mg packets should not be substituted for the 40 mg immediate-release omeprazole-bicarbonate packet.

<sup>d</sup> No published information; based on omeprazole data.

<sup>e</sup> Dexlansoprazole is available as a dual delayed-release formulation in capsules for oral administration. The capsule contains dexlansoprazole in a mixture of two types of enteric-coated granules with different pH-dependent dissolution profiles.

Data from references 52, 70, and 72.
performed by the manufacturer and submitted to the FDA, as well as warnings regarding omeprazole, esomeprazole, and other interacting drugs (e.g., cimetidine) are contained in the clopidogrel package insert. A reduced antiplatelet effect of clopidogrel may also result from genetic polymorphisms of the CYP2C19 pathway leading to decreased biotransformation of the drug to its active form. Whether the use of other PPIs such as pantoprazole, lansoprazole, deslansoprazole, and rebeprazole interact with clopidogrel remains uncertain as the capacity to inhibit CYP2C19 varies among these PPIs. While some reports suggest a “class effect” among the different PPIs, other pharmacodynamic studies suggest an interaction with omeprazole and esomeprazole but not with pantoprazole. Because of the uncertainty of the effect of the PPI-clopidogrel interaction on clinical outcomes and the extent to which other PPIs may interact with clopidogrel, caution is warranted. Until more compelling data becomes available, patients should have an acceptable indication for a PPI recognizing that risk versus benefit must be weighed on an individual basis. If a PPI is absolutely necessary, the use of omeprazole and esomeprazole should be avoided.

### CLINICAL CONTROVERSY

Some clinicians believe that the antiplatelet effect of clopidogrel is attenuated by omeprazole and that there is an increased risk of adverse cardiac events when these medications are taken concomitantly. Strategies to avoid this interaction for patients at risk of NSAID-related GI events include switching omeprazole to another PPI or substituting an H2RA for the PPI. Others believe that the use of a PPI (if indicated) and clopidogrel is not a safety concern and that it is not necessary to switch omeprazole to another PPI.

### Potential Risks and Long-Term Safety Issues

Numerous potential risks and safety issues (see Table 40–12) have been associated with the long-term use of PPIs as a consequence of prolonged hypergastrinemia and chronic hypochlorhydria. In most cases, causality is difficult to ascertain because of the study design, confounding variables, and subject selection. All of the PPIs dose-dependently increase serum gastrin concentrations two- to fourfold as a function of their potent acid-inhibitory effect. Fasting gastrin elevations are usually within the normal range and return to baseline within 1 month of discontinuing the drug. In humans, PPIs may lead to enterochromaffin-like (ECL) hyperplasia as a result of the hypergastrinemia, but there is no evidence that these changes result in dysplasia, carcinoid tumors, or gastric adenocarcinoma. Although long-term PPI therapy in *H. pylori*-positive individuals is associated with progressive atrophic gastritis, there is insufficient data to link chronic PPI use with gastric cancer in *H. pylori*-positive patients. Despite theoretical and in vitro data, there is no evidence to support an association between PPIs and colonic polyps or colorectal cancer. Bacterial overgrowth occurs in the stomach as a consequence of hypochlorhydria and may lead to carcinogenic N-nitroso compounds in animals but is unlikely to result in significant gastric nitrosation in humans.

Chronic PPI therapy may be associated with an increased risk of infection and nutritional deficiencies. Gastric acid (low stomach pH) plays an important role in the defense against bacterial colonization of the stomach and in nutrient absorption. Acid suppression has been implicated as a risk factor for community acquired pneumonia (CAP) and enteric infections (Clostridium difficile, Salmonella, Campylobacter). Three case-controlled studies demonstrate a higher adjusted relative risk of CAP for patients currently using PPIs compared with controls. The results of these retrospectively designed studies, however, need to be interpreted cautiously because of the variability in the length of therapy for current PPI users and the inclusion of older (>60 years of age) patients with concomitant comorbidities. A systematic review of the literature has linked PPIs with various enteric infections, but the most convincing data was with *C. difficile*. It is likely that sustained elevations in intragastric pH facilitate the survival of *C. difficile* spores. However, the magnitude of risk varies and causality is difficult to establish. The risk of various infections associated with PPI therapy can not be firmly established until the results of large prospective studies are made available.

The absorption of Vitamin B12, dietary iron, and calcium requires an acidic environment and may be adversely affected by PPI-induced prolonged hypochlorhydria. Although a few studies have investigated the long-term use of PPIs on Vitamin B12 and iron absorption, the clinical importance of their effect on absorption has not been established, and monitoring of B12 and iron levels cannot be recommended. However, adequate supplementation and monitoring should be considered in high risk populations (e.g., older patients, vegetarians, alcoholism) who may be already depleted. High PPI dosage and long-term therapy have been associated with an increased risk of hip, wrist and spine fractures related to reduction in calcium absorption. Although the results of the studies vary, the FDA has revised the warnings and precautions of prescription and nonprescription PPIs to reflect this potential risk. Bone density tests for osteoporosis screening, calcium supplementation, or other precautions cannot be recommended solely based on chronic PPI therapy. However, it is appropriate to screen and treat older patients for osteoporosis regardless of whether they are receiving long-term PPI therapy.

### H2-Receptor Antagonists

Ulcer healing is comparable among H2RAs (cimetidine, famotidine, nizatidine, and ranitidine) with equipotent multiple daily doses or a single full dose given after dinner or at bedtime (see Table 40–9), but tolerance to their antisecretory effect may occur. Twice-daily administration suppresses daytime acid and benefits patients with daytime ulcer pain. Cigarette smokers may require higher doses or a longer duration of treatment. H2RAs are eliminated renally and therefore a dosage reduction is recommended for patients with moderate to severe renal failure. The short- and long-term safety of all four H2RAs is similar. Thrombocytopenia, the most common...
hematologic adverse effect, is reversible and occurs with all four H$_2$RAs. However, the propensity for H$_2$RAs to cause thrombocytopenia is likely overestimated. Cimetidine inhibits several CYP450 isoenzymes, resulting in numerous drug interactions (e.g., theophylline, lidocaine, phenytoin, warfarin, and clopidogrel). Ranitidine has less potential for hepatic CYP450 drug interactions, while famotidine and nizatidine do not interact with drugs metabolized by the hepatic CYP450 pathway. The H$_2$RAs decrease acid secretion and may alter the bioavailability of orally administered drugs, similar to that seen with the PPIs.

### Sucrefate
Sucrefate heals peptic ulcers, but is not widely used today for this indication. Deterrents to its use include the requirement for multiple doses per day, large tablet size, and the need to separate the drug from meals and potentially interacting medications. Drug interactions can be minimized by giving the interacting drug at least 2 hours before sucrefate. Alternative therapy is warranted for patients taking oral fluoroquinolones. Constipation may be troublesome especially in older individuals. Seizures may occur in dialysis patients taking aluminum-containing antacids. Hypophosphatemia may develop with long-term treatment. Gastric bezoar formation has also been reported.

### Prostaglandins
Misoprostol, a synthetic prostaglandin E$_1$ analog, moderately inhibits acid secretion and enhances mucosal defense. Antisecretory effects are dose dependent over the range of 50 to 200 mcg; cytoprotective effects occur in humans at doses of greater than 200 mcg. Because protective effects occur at higher doses, it is difficult to establish the protective effect independent of the antisecretory action. Although not recommended in the United States, a dose of 200 mcg 4 times daily or 400 mcg twice daily heals duodenal ulcers and gastric ulcers comparable to standard H$_2$RA or sucrefate regimens. Diarrhea, the most troublesome adverse effect, is dose dependent and develops in 10% to 30% of patients. Abdominal cramping, nausea, flatulence, and headache typically accompany the diarrhea. Taking the drug with or after meals and at bedtime may minimize the diarrhea. Misoprostol is contraindicated in pregnant women because it is uterotrophic and produces uterine contractions that may endanger pregnancy. Misoprostol is prescribed to women in their childbearing years, contraceptive measures must be confirmed and a negative serum pregnancy test should be documented within 2 weeks of initiating treatment. Patients should be counseled about the GI effects and the need to avoid magnesium antacids, as they may increase the propensity for GI adverse effects.

### Bismuth Preparations
Bismuth subsalicylate and bismuth subcitrate potassium (biskaltrate) are the only available bismuth salts in the United States. Possible ulcer-healing mechanisms include an antibacterial effect, a local gastroprotective effect, and stimulation of endogenous prostaglandins. Bismuth salts do not inhibit or neutralize acid. Bismuth subsalicylate is regarded as safe and has few adverse effects when taken in recommended dosages. Because renal insufficiency may decrease bismuth elimination, bismuth salts should be used with caution in older patients and in renal failure. Bismuth subsalicylate may cause salicylate sensitivity or bleeding disorders and should be used with caution for patients receiving concurrent salicylate therapy. Bismuth salts impart a black color to stool and possibly the tongue (liquid preparations).

### Antacids
Antacids neutralize gastric acid, inactivate pepsin, and bind bile salts. Aluminum-containing antacids also suppress $H. pylori$ and enhance mucosal defense. The GI adverse effects are most common and are dose dependent. Magnesium salts cause an osmotic diarrhea, whereas aluminum salts cause constipation. Diarrhea usually predominates with magnesium/aluminum preparations. Aluminum-containing antacids (except aluminum phosphate) form insoluble salts with dietary phosphorus and interfere with phosphorus absorption. Hypophosphatemia occurs most often for patients with low dietary phosphate intake (e.g., malnutrition or alcoholism). Combined treatment with sucrefate may amplify the hypophosphatemia and aluminum toxicity.

Magnesium-containing antacids should not be used for patients with a creatinine clearance of less than 30 mL/min because magnesium excretion is impaired, which may lead to toxicity. Hypercalcemia may occur for patients with normal renal function taking more than 20 g/day of calcium carbonate and for patients with renal failure who are taking more than 4 g/day. The milk–alkali syndrome (hypercalcemia, alkalosis, renal stones, increased blood urea nitrogen, and increased serum creatinine concentration) occurs with high calcium intake for patients with systemic alkalosis produced by either ingestion of absorbable antacids (sodium bicarbonate) or prolonged vomiting. Antacids may alter the absorption and excretion of drugs when administered concomitantly.

Drug interactions may occur when antacids are administered with iron, warfarin, tetracycline, digoxin, quinidine, isoniazid, ketoconazole, or the fluoroquinolones. Most interactions can be avoided by separating the antacid from the oral drug by at least 2 hours.

### Pharmacoeconomic Considerations
The eradication of $H. pylori$ improves clinical outcomes and decreases the use of healthcare resources when compared with conventional antisecretory therapy. Thus the costs of continued treatment and recurrence far outweigh the cost of $H. pylori$ drug regimens. The cost-effectiveness of misoprostol cottherapy is greatest for patients with the highest risk for NSAID-related GI complications. The addition of a PPI to both nonselective and partially selective NSAIDs or selective COX-2 inhibitor NSAIDs (if available) is highly cost-effective even for patients with low GI risk especially when the least expensive PPI is used.

### EVALUATION OF THERAPEUTIC OUTCOMES
Table 40–13 lists the recommendations for treating and monitoring patients with PUD. Relief of epigastric pain should be monitored throughout the course of treatment for patients with either $H. pylori$- or NSAID-related ulcers. Ulcer pain typically resolves in a few days when NSAIDs are discontinued and within 7 days upon initiation of antiulcer therapy. Most patients with uncomplicated PUD will be symptom free after treatment with any one of the recommended antiulcer regimens. The persistence, or recurrence, of symptoms within 14 days after the end of treatment suggests failure of ulcer healing or $H. pylori$ eradication or an alternative diagnosis such as GERD. Most patients with uncomplicated $H. pylori$–positive ulcers do not require confirmation of ulcer healing or $H. pylori$ eradication. However, eradication should be confirmed after treatment in individuals who are at risk for complications, for example, individuals who had a prior bleeding ulcer. The UBT is the preferred test to confirm $H. pylori$ eradication when endoscopy is not indicated. Medication adherence should be assessed for patients who fail therapy. Because a large number of at-risk patients treated with NSAIDs do not receive adequate prophylaxis for GI complications, therapeutic outcomes can be improved by advocating preventive strategies. Patients on NSAIDs should be closely monitored for signs or symptoms of bleeding, obstruction, penetration, or perforation. A follow-up endoscopy is justified for patients with frequent symptomatic recurrence, refractory disease, complications, or suspected hypersecretory states.

**ZOLLINGER-ELLISON SYNDROME (ZES)**

ZES is characterized by gastric acid hypersecretion and recurrent peptic ulcers that result from a gastrin-producing tumor (gastrinoma). In the United States, ZES accounts for 0.1% to 1% of patients with duodenal ulcer; however, this may be an underestimation of the true incidence because of the heterogeneity of clinical manifestations. Gastrinomas are classified as those associated with multiple endocrine neoplasia type 1 (MEN 1) or sporadic tumors, which have a greater tendency to behave as malignant tumors. In more than 80% of cases, gastrinomas are localized in an area referred to as the triangle of gastrinomas, which includes the convergence of the cystic duct and the common bile duct, the junction of the second and third portion of the duodenum, and the junction of the head and body of the pancreas. More than 50% of the gastrinomas malignant, often with metastases to regional lymph nodes, liver, and bone.

**UPPER GASTROINTESTINAL BLEEDING**

There are about 160 cases of upper GI bleeding per 100,000 adults annually in the United States. Despite a decreased incidence of PUD and improvements in the management of upper GI bleeding, the mortality rate associated with acute hemorrhage remains between 5% and 15%. Upper GI bleeding is categorized as variceal or nonvariceal bleeding. Two common types of nonvariceal bleeding are bleeding from chronic peptic ulcers and bleeding from SRMD (stress gastritis, stress ulcer, or stress erosions), both of which are acid–peptic complications. Upper GI bleeding associated with chronic PUD usually precedes hospital admission, whereas bleeding associated with SRMD develops in severely ill patients during hospitalization.

The underlying pathophysiology of bleeding from a peptic ulcer or from SRMD is similar in that impaired mucosal defense in the presence of gastric acid and pepsin leads to mucosal...
section of SRMD in critically ill patients is thought to be mucosal ischemia which is a result of reduced gastric blood flow. Defense mechanisms are normally in place to protect the gastric mucosa against the damaging effects of gastric acid, pepsin, and bile (see the section Pathophysiology of Chronic PUD). However, these defense mechanisms become diminished in the face of the overwhelming physiologic stress from critical illness and coupled with mucosal ischemia and subsequent reperfusion injury along with gastric acid result in the rapid development of mucosal lesions. In contrast to chronic PUD, stress-related mucosal lesions are characteristically asymptomatic, numerous, located in the proximal stomach, and are unlikely to perforate. Bleeding from SRMD occurs from superficial mucosal capillaries, whereas bleeding associated with chronic PUD usually results from a single vessel.

The mortality rate associated with clinically important SRMB is approximately 50% and is related to the underlying severity of disease and comorbidities in this patient population. In contrast, the mortality associated with chronic PUD-related bleeding is approximately 10% but can increase dramatically in select patient populations. Although the initial management of acute upper GI bleeding focuses on aggressive resuscitative measures and ensuring hemodynamic stability, the medical management of PUD-related bleeding and SRMB is distinctly different.

**PEPTIC ULCER-RELATED BLEEDING**

The most common presenting signs and symptoms of PUD-related bleeding are hematemesis (vomiting up blood) or melena (dark, tarry stools) or possibly both. When evaluating patients with PUD-related bleeding, the degree of risk for adverse outcomes must be rapidly assessed in order to determine if the patient’s condition constitutes a medical emergency. Two risk-stratification tools exist for early assessment and triage. The Blatchford score is a newer risk-stratification scale and is used to evaluate the need for urgent endoscopic intervention for patients presenting with PUD-related bleeding. The scale values range from 0 to 23, with higher scores indicating higher risk. The most well-known scale, however, is the Rockall Score. This validated risk-assessment instrument is composed of two assessments: the clinical score, which is performed prior to endoscopy, and the endoscopic score. The use of these risk-stratification tools can reduce the requirement of endoscopic procedures and lead to early discharge for low-risk patients while ensuring rapid intervention for patients at higher risk. These data will also allow the pharmacist to make appropriate pharmacotherapy decisions based on the patient’s assessed level of risk. When considering the risk of death due to PUD-bleeding, the following patients generally have poorer prognoses and usually require more aggressive intervention including admission to an intensive care unit (ICU).

- Older than 60 years of age
- Comorbid conditions (e.g., ischemic heart disease, congestive heart failure, renal failure, hepatic failure, metastatic cancer)
- High transfusion requirements
- Ongoing blood loss
- Presence of hypovolemic shock (i.e., tachycardia with a pulse of ≥100 beats per minute, hypotension with a systolic blood pressure of <100 mmHg with concomitant orthostatic changes, such as an increase in the heart rate of ≥20 beats per minute or decrease in systolic blood pressure of ≥20 mmHg upon standing from a sitting position)
- Prolonged prothrombin time [or increased international normalized ratio (INR)]
- Erratic mental status

Initial therapy for patients with defined hemostatic instability should focus on correcting fluid volume loss though appropriate volume resuscitative measures. This is usually accomplished with a continuous 0.9% sodium chloride infusion (or blood products if clinically indicated) through two large bore peripheral intravenous catheters (i.e., 16 to 18 gauge). The use of nasogastric (NG) tubes remains controversial but may aid in early assessment and gastric lavage.

Diagnostic endoscopy is usually performed as early as possible (preferably within 24 hours of presentation) to identify the source of the bleeding, assess the potential risk for rebleeding, and, if appropriate, employ therapeutic interventions to promote hemostasis. Several endoscopic treatment approaches (e.g., thermocoagulation, laser therapy, injection sclerotherapy, hemoclipping, and ligation) can be used; however, to maximize the likelihood of positive outcomes, patients are usually treated with a combination of thermocoagulation and injection of lesions with epinephrine. The appearance of the ulcer at the time of endoscopy is a prognostic indicator for the risk of rebleeding. Clean-based and flat spot (pigmented) ulcers are most commonly seen and are associated with a low risk of rebleeding (5% and 10%, respectively). In most cases, patients with clean base ulcers can be immediately discharged after endoscopy on antiulcer therapy (usually twice daily PPI), while patients with flat spot ulcers may be admitted to the general hospital ward for a brief observation period. Patients with an adherent clot overlying the ulcer base are at intermediate risk of rebleeding (22%), and controversy exists as to the appropriate management of these patients. Adherent clots can be removed, and then the lesion be reclassified based on what is observed following clot removal. Patients with a visible vessel or active bleeding are at the highest risk of rebleeding (43% and 55%, respectively) and should be managed within an ICU for at least 24 hours and then monitored on a general medical/surgical service for an additional 48 hours (total of 72 hours), as rebleeding significantly increases mortality.

Antisecretory therapy is often used as adjuvant therapy to endoscopic procedures to prevent PUD rebleeding in high-risk patients because acid impairs clot stability. However, endoscopic hemostasis techniques remain the treatment of choice for patients with life-threatening bleeding, as this has been associated with better outcomes when compared with either placebo or pharmacotherapy. H₂-Receptor antagonists are ineffective in preventing PUD rebleeding because they do not achieve an intragastric pH of 6 (which is needed to promote hemostasis and clot stability) and tolerance to their antisecretory effect develops rapidly (especially with high dose or intravenous therapy). In contrast, PPIs reduce the incidence of rebleeding and need for surgery but have no significant impact on overall mortality. Interestingly, subgroup analysis from two differing metaanalyses has suggested a mortality benefit with high-dose intravenous PPIs in a subgroup of patients with the highest risk of rebleeding (i.e., nonbleeding visible vessel or active bleeding).

The precise route (oral or intravenous) and the dose of PPI should be based on the clinical situation, risk of rebleeding, endoscopic identification of the lesion, and patient risk. Because of the theoretical goal of maintaining intragastric pH values >6, and data from randomized, controlled trials, practice guidelines recommend that high-dose continuous infusion PPI (equivalent to omeprazole 80 mg given intravenously as a loading dose, followed by 8 mg/h continuous infusion for 72 hours) be used to reduce the risk of rebleeding in high-risk patients who have undergone...
endoscopy hemostasis. 102,103,134,135 Because intravenous omeprazole is not available in the United States and three small randomized, controlled trials have not demonstrated any evidence of improved outcomes between the available intravenous PPIs and omeprazole, most clinicians consider intravenous pantoprazole and esomeprazole to be equivalent to intravenous omeprazole on a milligram-per-milligram basis. Thus, intravenous pantoprazole and esomeprazole can be interchanged as there is currently no evidence to suggest that one PPI is superior to another. 115,117 The administration of high-dose continuous-infusion PPIs given prior to endoscopy hastens resolution of bleeding stigmata. 119 However, PPI therapy is not a replacement for interventional endoscopy for patients who are at high risk of rebleeding, as data demonstrate that the combination of a high-dose PPI continuous intravenous infusion with therapeutic endoscopy is superior to either strategy alone. 119,121

High-dose oral PPI therapy (omeprazole 80 mg/day for 5 days) is also effective; however, concerns exist as to whether critically ill patients will absorb the medication. 106,114 The risk of rebleeding is greatest within the first 72 hours (especially the first 24 hours), and it is during this time that antisecretory therapy to prevent rebleeding in high-risk patients should be employed. 102,106 Patients should be transitioned to an oral PPI upon completion of intravenous therapy. Somatostatin or octreotide have not demonstrated any significant benefit in treating nonvariceal bleeding and are not recommended at this time. 102,106

Patients with upper GI bleeding should be tested for H. pylori at the time of endoscopy (see Tests for Helicobacter Pylori). However, the tests are associated with an increased rate of false-negatives when obtained during acute bleeding episodes. 120 If the initial results of the rapid urease test and/or histology are negative, a confirmatory test (14C-urea breath test or serology) should be performed following the acute bleeding episode. There is no rationale for using intravenous therapy to eradicate H. pylori. Ulcer treatment, including H. pylori eradication, if appropriate, should be initiated after the acute bleeding episode has resolved (see Treatment of Helicobacter Pylori–Associated Ulcers and Treatment of NSAID-Induced Ulcers).

STRESS-RELATED MUCOSAL BLEEDING

Critically ill patients may develop SRMD leading to SRMB because of the homeostatic compromise that is associated with severe illness. 106,107 More than 75% (some studies suggesting up to 100%) of critically ill patients develop SRMD within the first 1 to 3 days of admission to an ICU, but the incidence of clinically important SRMB (defined as overt bleeding with concomitant hemodynamic instability and likely requirement for blood products) is 1% to 4%. 106,107,122 Clinically important bleeding increases the length of ICU stay by up to 11 days, results in excessive healthcare costs and is associated with increased mortality. 107,106,107,122 Thus, attempts to prevent SRMB are warranted in high-risk patients. Prophylactic therapy to prevent bleeding is most effective if initiated early in the patient’s course.

- Patients who are at risk for SRMB include those with respiratory failure (need for mechanical ventilation for longer than 48 hours), coagulopathy (INR >1.5, platelet count <50,000/mm3), hypotension, sepsis, hepatic failure, acute renal failure, high-dose corticosteroid therapy (>250 mg/day hydrocortisone or equivalent), multiple trauma, severe burns (>35% of body surface area), head injury, traumatic spinal cord injury, major surgery, prolonged ICU admission (>7 days), or history of GI bleeding. 105,106,122 The relative importance of the various risk factors remains controversial, but most clinicians concur that patients with respiratory failure or coagulopathy should receive prophylaxis, as these two factors are independent risk factors for SRMB. 105,106 In the absence of these risk factors, some clinicians only administer prophylaxis to patients who have two of the aforementioned risk factors. 105 Since not all patients in a hospital or ICU are at increased risk of SRMB, a cost-effective approach should be developed to target prophylactic therapy at high-risk patients.

Some clinicians feel that stress-related mucosal bleeding prophylaxis is indicated for all critically ill patients given the associated mortality and increased length of stay for patients who develop this complication. Others adhere to clinical guidelines that suggest only high-risk patients such as those with respiratory failure requiring ventilation or patients with coagulopathy and perhaps those patients with two or more other risk factors will benefit from prophylaxis.

Prevention of SRMB includes resuscitative measures that restore mucosal blood and pharmacotherapy that either maintains an intragastric pH of >4 or provides gastric mucosal protection. 106–107 Although the benefits of enteral nutrition to patient outcome (e.g., improved nutritional status enhances mucosal integrity) are of overall clinical importance, its precise role as a sole modality to prevent SRMB remains controversial. 106–107 Therapeutic options for the prevention of SRMB include antacids (which are of historical interest, as they are no longer used because of cumbersome dosage schedules and side effects), antisecretory drugs (H2RAs and PPIs), and sucralfate (mucosal protectant). 105–107,109,122

Antisecretory therapy is generally preferred for SRMB prophylaxis for several reasons. First, a large landmark study demonstrated that intravenous ranitidine was superior to oral sucralfate in preventing SRMB. 123 Second, ranitidine did not increase the risk for nosocomial pneumonia, as the incidence of pneumonia was not different between the two treatment groups. 123 Third, although sucralfate is an evidence based option, it is cumbersome, requiring multiple daily dosage administration (up to 4 times daily), which may occlude nasogastric tubes, cause constipation, interact with several medications, and/or increase the potential for aluminum toxicity in patients with renal dysfunction. Finally, sucralfate does not have any appreciable effect on reducing intragastric pH. Although data published in 2004 indicated that H2RAs were the most commonly prescribed antisecretory agents used to prevent SRMB, 124 it is now estimated that PPIs have become the mainstay of therapy. 106 Regardless, numerous studies and years of experience support the use of H2RAs, and they remain a recommended option for the prevention of SRMB.

Parenteral H2RAs may be administered as either continuous infusions or intermittent bolus doses (see Table 40–14). Cimetidine, given as a continuous intravenous infusion, is the only FDA-labeled H2RA for the prevention of SRMB. Despite evidence suggesting that continuous infusions of the H2RAs are superior to intermittent dosing at maintaining an intragastric pH >4, there is no evidence to suggest better outcomes with respect to prevention of SRMB. 106 Thus, intermittent bolus doses of H2RAs are used more commonly than continuous infusions. 107,109 Drug interactions are more common with cimetidine, and for this reason the other H2RAs (famotidine, ranitidine) are used more frequently. 106 Adverse events associated with the use of H2RAs for the critically ill patient include thrombocytopenia, mental status changes (more common in older patients or individuals with renal or hepatic compromise), and tachyphylaxis (especially with parenteral or high dose therapy). 106 Given that the H2RAs are renally eliminated, dosage reductions are recommended for patients with renal dysfunction.

*Product in FDA approved for the prevention of stress-related mucosal bleeding.

**a** Administered as an extemporaneously compounded suspension made with sodium bicarbonate.

**b** Administered as a rapidly disintegrating tablet given orally or by NG dissolved in 10 mL of water.

The PPIs are more potent than H2RAs in inhibiting acid secretion and, unlike H2RAs, tolerance does not develop.106,107,109,122 Although there are limited data assessing the efficacy of PPIs for the prevention of SRMB, recent reports suggest that PPIs may be used as alternatives to H2RAs or sucralfate.122,125,126 Initial open-label studies of PPIs for SRMB prophylaxis were performed with omeprazole compounded suspensions given as 40 mg for two doses on the first day, followed by 20 mg/day thereafter in critically ill or trauma patients requiring mechanical ventilation and the presence of at least one additional risk factor.127,128 The results of these studies demonstrated significant pH control above 4 and no GI bleeding in either trial. Because of the small number of subjects, no firm clinical outcomes can be derived from these studies. Since then, numerous extemporaneously compounded sodium bicarbonate suspensions of PPIs (see Table 40–11) have been used as cost-effective regimens for stress ulcer prophylaxis in patients with NG tubes.106,109,122,129 In one study, immediate-release omeprazole–sodium bicarbonate suspension (40 mg × 2 doses, then 40 mg/day) was more effective than continuous infusion cimetidine in maintaining intragastric pH >4 in critically ill patients, but there was no difference in the incidence of clinically important SRMD between the two groups.133 Based on meeting the prespecified criteria for noninferiority, immediate-release omeprazole gained FDA labeling for the prevention of SRMB.134 In another trial of ICU patients requiring mechanical ventilation, patients were randomized to receive either lansoprazole 30 mg given as a rapidly disintegrating tablet mixed in 10 mL of water and administered via an NG tube or lansoprazole 30 mg given as an intravenous infusion (no longer available in the United States) once daily for 72 hours.135 Enterally administered lansoprazole, despite having a lower bioavailability, resulted in superior intragastric pH control when compared with the intravenously administered lansoprazole.

One of the most compelling dose-finding pilot studies to evaluate the use of intravenous PPIs for SRMB prophylaxis was performed in over 200 ICU patients examining five different dosing strategies of pantoprazole (40 mg given every 8 hours, every 12 hours, and every 24 hours or 80 mg given every 12 hours or every 24 hours) versus cimetidine given as a 300 mg intravenous bolus followed by a 50 mg/h continuous infusion.125 Each regimen was given for at least 48 hours and for up to 7 days. The time the intragastric pH was ≥4 increased from day 1 to day 2 in all the pantoprazole groups, whereas it actually decreased in the cimetidine group suggesting tachyphylaxis. No bleeding was identified in any of the treatment groups. The results suggest appropriate pH control can be obtained with doses of 80 mg given on day 1 and 40 mg given every 12 hours thereafter. The use of intravenous esomeprazole has also demonstrated efficacy in a small number of clinical studies.106 Given the relatively limited data, the overall efficacy, optimal dosage, frequency, and route of administration for PPIs in the prevention of SRMB remains to be fully elucidated.106,107 Based on the available evidence, several PPI dosing regimens for SRMB prophylaxis exist (see Table 40–14). Adverse events that have been described when the PPIs are used for this indication include an increased risk of enteric infections, including C. difficile associated diarrhea and nosocomial pneumonia.106

1 When deciding on the most appropriate pharmacotherapy plan for the prevention of SRMB for a specific patient, the clinical presentation of the patient and medication costs should be used as a guide. Patients who can take oral medication or have a working NG tube in place may be placed on an oral or compounded PPI suspension as a cost-effective measure. For most patients who are not able to utilize one of these routes, an intravenous H2RA is appropriate. However, if the patient has renal dysfunction, develops thrombocytopenia, or mental status changes while on an H2RA, then an intravenous PPI may be the most appropriate prophylaxis option. Consideration should be given to both the patient’s clinical condition as well as the most cost effective option when developing protocols for preventing SRMB.

Improvement in the patient’s overall medical condition (resolution of risk factors, discharge from the ICU, extubation, and oral intake) suggests that prophylactic therapy can be discontinued.106 Too often the patient is continued on SRMB prophylaxis upon transition to the general medical/surgical unit and is often discharged on oral PPI therapy without an appropriate indication.131 This results in unnecessary costs for the patient and the healthcare system.131 Pharmacists should identify patients in which SRMB prophylaxis is no longer indicated.106 If a patient develops clinically important bleeding, endoscopic evaluation of the GI tract is indicated along with aggressive antisecretory therapy (see the section Peptic Ulcer-Related Bleeding).

**ABBREVIATIONS**

BAO: basal acid output
COX-1: cyclooxygenase-1
COX-2: cyclooxygenase-2
CYP450: cytochrome P450
ECL: enterochromaffin-like
ELISA: enzyme-linked immunosorbent assay
GERD: gastroesophageal reflux disease
H. pylori: Helicobacter pylori
H2RA: histamine-2 receptor antagonist
ICU: intensive care unit
MALT: mucosa-associated lymphoid tissue
MALT: mucosa-associated lymphoid tissue
MEN: multiple endocrine neoplasia
MEN: multiple endocrine neoplasia
NUD: nonulcer dyspepsia
NSAID: nonsteroidal antiinflammatory drug
NG: nasogastric
NUD: nonulcer dyspepsia
PG: prostaglandin
PPI: proton pump inhibitor

CHAPTER 41

Inflammatory Bowel Disease

BRIAN A. HEMSTREET

KEY CONCEPTS

1. The exact cause of inflammatory bowel disease (IBD) is unknown, although there are components that appear to be infectious and other components that suggest immune dysregulation. Genetic variations explain some of the increased risk of disease occurrence.

2. Ulcerative colitis (UC) is confined to the rectum and colon, causes continuous lesions, and affects primarily the mucosa and the submucosa. Crohn’s disease (CD) can involve any part of the gastrointestinal (GI) tract, often causes discontinuous (skip) lesions, and is a transmural process that can result in fistulas, perforations, or strictures.

3. Common GI complications of IBD include rectal fissures, fistulas (CD), perirectal abscess (UC), and colon cancer, while possible extraintestinal manifestations include hepatobiliary complications, arthritis, uveitis, skin lesions (including erythema nodosum and pyoderma gangrenosum), and aphthous ulcers of the mouth.

4. The severity of UC may be assessed by stool frequency, presence of blood in stool, fever, pulse, hemoglobin, erythrocyte sedimentation rate, C-reactive protein, abdominal tenderness, and radiologic or endoscopic findings. The severity of CD can be assessed using similar parameters, in addition to the CD activity index, which includes stool frequency, presence of blood in stool, endoscopic appearance, and physician’s global assessment.

5. The goals of IBD treatment are resolution of acute inflammation and complications, alleviation of systemic manifestations, maintenance of remission, and for some patients surgical palliation or cure.

6. The first line of treatment for mild to moderate UC or Crohn’s colitis consists of oral aminosalicylates, such as sulfasalazine or mesalamine; mesalamine or steroid enemas or suppositories may be used for distal disease. Certain delayed-release oral formulations of mesalamine may be used for Crohn’s ileitis. Controlled-release budesonide may be used for CD confined to the ileum and/or ascending colon.

7. Corticosteroids are often required for acute UC or CD. The duration of steroid use should be minimized and the dose tapered gradually over 3 to 4 weeks.

8. Infliximab is a treatment option for patients with moderate to severe active UC and for those patients with UC who are dependent on corticosteroids. Azathioprine or mercaptopurine may be used for maintenance of remission as an alternative to infliximab for patients with UC who have failed aminosalicylates and for patients who are corticosteroid dependent.

9. Intravenous continuous infusion of cyclosporine may be effective in treating severe colitis that is refractory to corticosteroids as an option to delay or prevent the need for surgery.

10. Sulfasalazine and mesalamine derivatives can prevent recurrence of acute disease in many patients, while steroids are ineffective for this purpose.

11. Other drugs that are useful for treatment of CD include infliximab, adalimumab, and certolizumab (for moderate to severe or fistulizing disease); methotrexate, azathioprine, or mercaptopurine (for inadequate response or to reduce steroid dosage); metronidazole (for perineal disease); and cyclosporine (for refractory disease).

There are two forms of idiopathic IBD: (1) UC, a mucosal inflammatory condition confined to the rectum and colon, and (2) CD, a transmural inflammation of the GI tract that can affect any part, from the mouth to the anus. The etiologies of both conditions are unknown, but they may have some common pathogenic mechanisms.

EPIDEMIOLOGY

Inflammatory bowel disease (IBD) is most prevalent in Western countries and in areas of northern latitude.1 The reported rates of IBD are highest in Scandinavia, Great Britain, and North America.2 Crohn’s disease (CD) has an incidence of 3.6 to 8.8 per 100,000 persons in the United States and a prevalence of 20 to 40 per 100,000 people.1,3 The incidence of CD varies considerably among studies, but has clearly increased dramatically over the last 3 or 4 decades.3,4 Ulcerative colitis (UC) incidence ranges from 3 to 15 cases per 100,000 persons per year among the white population with a prevalence of 80 to 120 per 100,000.1 The incidence of UC has remained relatively constant over many years.5 Although most epidemiologic studies combine ulcerative proctitis with UC, 17% to 49% of cases are classified as proctitis.

Both sexes are affected equally with IBD, although some studies show slightly greater numbers of women with CD and males with UC.2 UC and CD have bimodal distributions in age of initial

### ETIOLOGY

Although the exact etiology of UC and CD is unknown, similar factors are believed responsible for both conditions (Table 41–1). The major theories of the cause of IBD involve a combination of infectious, genetic, and immunologic factors. The inflammatory response with IBD may indicate abnormal regulation of the normal immune response or an autoimmune reaction to self-antigens. The microbiota of the gastrointestinal tract may provide an environmental trigger to activate inflammation. CD has been described as a disorder mediated by T lymphocytes that arise in genetically susceptible individuals as a result of a breakdown in the regulatory constraints on mucosal immune responses to enteric bacteria.

### INFECTIOUS FACTORS

Microorganisms are a likely factor in the initiation of inflammation in IBD. However, no definitive infectious cause of IBD has been found, even though the presentation is similar to that caused by some invasive microbial pathogens. Patients with IBD have increased numbers of surface-adherent and intracellular bacteria. IBD may involve a loss of tolerance toward normal bacterial flora. Other supporting evidence for an infectious etiology is that colitis does not appear to occur in genetically altered germ-free animals, intestinal lesions in IBD typically predominate in areas of highest bacterial exposure, and observed differences in the existing makeup of the resident luminal and mucosal bacterial flora in healthy subjects versus those with IBD.

Suspect infectious agents include the measles virus, protozoans, mycobacteria such as Mycobacterium paratuberculosis or avium, and other bacteria such as Listeria monocytogenes, Chlamydia trachomatis, and Escherichia coli. Clostridium difficile infection may lead to increases in frequency of relapses and enhanced severity of IBD. Also, certain strains of bacteria produce toxins (necrotxins, hemolysins, and enterotoxins) that cause mucosal damage. Bacteria elaborate peptides (e.g., formyl-methionyl-leucyl-phenylalanine) that have chemotactic properties and that cause an influx of inflammatory cells with subsequent release of inflammatory mediators and tissue destruction. Microbes may elaborate superantigens, which are capable of global T-lymphocyte stimulation and subsequent inflammatory response. As many as 60% of patients with CD have circulating antibody to *Saccharomyces cerevisiae*, but this may not represent a disease mechanism.

### GENETIC FACTORS

Genetic factors predispose patients to IBDs, particularly CD. In studies of monozygotic twins, there has been a high concordance rate, with both individuals of the pair having an IBD (particularly CD). Also, first-degree relatives of patients with IBD may have up to a 20-fold increase in the risk of disease. Several genetic markers have been identified that occur more frequently for patients with IBD. The CARD15 gene on chromosome 16, formerly referred to as NOD2, is thought to account for 20% of the genetic predisposition to CD. Likewise, polymorphisms of the interleukin 23 receptor (IL23R) are strongly associated with CD and possibly UC. Human leukocyte antigen (HLA) DR2 has been associated with UC in Japanese subjects, while HLA DR3 has been associated with UC in European subjects. Additionally the multidrug resistance gene 1 (ABCB/MDR 1) on chromosome 7 has been identified as a potential susceptibility gene for UC. As methods for identifying genetic variations have advanced, many other genes and single nucleotide polymorphisms have been associated with IBD, including DLG5, OCTN1, LC22A4, and CARD4, among others. This represents an intense area of research focus as identifying means to alter or prevent the disease process.

### IMMUNOLOGIC MECHANISMS

The immune system is known to play a critical role in the underlying pathogenesis of IBD. In CD the bowel wall is infiltrated with lymphocytes, plasma cells, mast cells, macrophages, and neutrophils. Similar infiltration has been observed in the mucosal layer of the colon in patients with UC. Inflammation in IBD is maintained by an influx of leukocytes from the vascular system into sites of active disease. This influx is promoted by expression of adhesion molecules (such as α4 integrins) on the surface of endothelial cells in the microvasculature in the area of inflammation. Many of the systemic manifestations of IBD have an immunologic etiology (e.g., arthritis or urethritis). Finally, IBD is typically responsive to immunosuppressive drugs (e.g., corticosteroids and azathioprine).

The immune theory of IBD assumes that IBD is caused by an inappropriate reaction of the immune system. Potential immunologic mechanisms include both autoimmune and nonautoimmune phenomena. Autoimmunity may be directed against mucosal epithelial cells or against neutrophil cytoplasmic elements. Some patients with IBD have abnormal structural features of colonic epithelial cells even in the absence of active disease. Autoantibodies to these structures have been reported. Also, antineutrophil cytoplasmic antibodies are found in a high percentage of patients with UC (70%) and much less frequently with CD. Presence of antineutrophil cytoplasmic antibodies in left-sided UC is associated with resistance to medical therapy. Dysregulation of cytokines is a component of IBD. Specifically, Th1 cytokine activity (which enhances cell-mediated immunity and suppresses humoral immunity) is excessive with CD, whereas Th2 cytokine activity (which inhibits cell-mediated immunity and enhances humoral immunity) is excessive with UC. The result is that patients have inappropriate T-cell responses to antigens from their own intestinal microflora. The IL23 pathway has also been implicated in clonal expansion of Th17 cells, which produce various proinflammatory cytokines. Expression of interferon-γ (a Th1 derived cytokine)
in intestinal mucosa of diseased patients is increased, while IL-4 (a Th2-derived cytokine) is reduced.\(^{7,21}\)

Tumor necrosis factor-\(\alpha\) (TNF-\(\alpha\)) is a pivotal proinflammatory cytokine in both CD and UC. TNF-\(\alpha\) can recruit inflammatory cells to inflamed tissues, activate coagulation, and promote the formation of granulomas. Production of TNF-\(\alpha\) is increased in the mucosa and intestinal lumen of patients with CD.\(^{7,10,21}\) Eicosanoids such as leukotriene B\(_4\) are increased in rectal dialyses and tissues of IBD patients and are related to disease activity. Leukotriene B\(_4\) enhances neutrophil adherence to vascular endothelium and acts as a neutrophil chemoattractant. These findings have led to the consideration of leukotriene inhibitor strategies for therapy.

**PSYCHOLOGICAL FACTORS**

Mental health changes appear to possibly correlate with remissions and exacerbations, especially of UC, but psychological factors overall are not thought to be an etiologic factor. There is a weak association between the number of stressful events experienced and the time to relapse of UC.\(^{22,23}\)

**DIET, SMOKING, AND NONSTEROIDAL ANTIINFLAMMATORY DRUG (NSAID) USE**

Changes in diet by people in industrialized countries where CD is more common have not been consistently associated with the disease. Studies of increased intake of refined sugars or chemical food additives and reduced fiber intake have provided conflicting results regarding risk for CD. Smoking plays an important but contrasting role in UC and CD.

Smoking appears to be protective for UC.\(^{10}\) The risk of developing UC in smokers is about 40\% of that in nonsmokers.\(^{2}\) Clinical relapses are associated with smoking cessation, and nicotine transdermal administration has been effective in improving symptoms for patients with UC.\(^{24}\) In contrast, smoking is associated with a twofold increased frequency of CD.\(^{3}\) Patients with CD who stop smoking have a more benign course than patients who continue smoking.\(^{25}\) The mechanisms of these differing effects have not been identified.

Use of NSAIDs may trigger disease occurrence or lead to disease flares.\(^{10,22,23}\) The effect of NSAIDs to inhibit prostaglandin production through cyclooxygenase inhibition may impair mucosal barrier protective mechanisms. The increased risk seems to be present for cyclooxygenase-2 inhibitors as well as cyclooxygenase-1 inhibitors; however, it is unclear whether cyclooxygenase-2 inhibitors may be somewhat safer in select patients with IBD.\(^{27,28}\) The use of NSAIDs may be warranted in some patients with IBD, particularly those with concomitant arthritic symptoms, if the benefit is thought to outweigh the potential risk of disease flare.\(^{23}\)

**PATHOPHYSIOLOGY**

UC and CD differ in two general respects: anatomic sites and depth of involvement within the bowel wall. There is, however, overlap between the two conditions, with a small fraction of patients showing features of both diseases. Confusion can occur, particularly when the inflammatory process is limited to the colon. Table 41–2 compares pathologic and clinical findings of the two diseases.

**ULCERATIVE COLITIS**

UC is confined to the rectum and colon and affects the mucosa and the submucosa. In some instances, a short segment of terminal ileum may be inflamed; this is referred to as *backwash ileitis*. Unlike CD, the deeper longitudinal muscular layers, serosa, and regional lymph nodes are not usually involved.\(^{10,11}\) Fistulas, perforation, or obstruction are uncommon because inflammation is usually confined to the mucosa and submucosa.

The primary lesion of UC occurs in the crypts of the mucosa (crypts of Lieberkühn) in the form of a crypt abscess. Here, frank necrosis of the epithelium occurs; it is usually visible only with microscopy but may be seen grossly when coalescence of ulcers occurs. Extension and coalescence ulcers may surround areas of uninvolved mucosa. These islands of mucosa are called *pseudopolyps*. Other typical ulceration patterns include a “collar-button ulcer,” which results from extensive submucosal undermining at the ulcer edge.\(^{10,28}\) The extensive mucosal damage seen in UC can result in significant diarrhea and bleeding, although a small percentage of patients experience constipation.

UC can be accompanied by complications that may be local (involving the colon or rectum) or systemic (not directly associated with the colon). With either type the complications may be mild, serious, or even life threatening. Local complications occur in the majority of UC patients. Other complications include hemorrhoids, anal fissures, or perirectal abscesses and are more likely to be present during active colitis. Enterocutaneous fistulas are rare.

A major complication is toxic megacolon, which is a segmental or total colonic distension of greater than 6 cm with acute colitis and signs of systemic toxicity.\(^{19}\) It is a severe condition that occurs in up to 7.9\% of UC patients admitted to hospitals and results in death rates of up to 50\%. With toxic megacolon, ulceration extends below the submucosa, sometimes even reaching the serosa. Vasculitis, swelling of the vascular endothelium, and thrombosis of small arteries occur; involvement of the muscularis propria causes loss of colonic tone, which leads to dilatation and potential perforation. The patient with toxic megacolon usually has a high fever, tachycardia, distended abdomen, and elevated white blood cell count, and a dilated colon is observed on x-ray.\(^{7,31}\) Colonic perforation, however, may occur with or without toxic megacolon and is a greater risk with the first attack. Another infrequent major local complication is massive colonic hemorrhage. Colonic stricture, sometimes with clinical obstruction, may also complicate long-standing UC.

The risk of colonic carcinoma is much greater for patients with UC as compared with the general population and begins to increase

10 to 15 years after the diagnosis of UC. The absolute risk may be as high as 30% to 35 years after diagnosis and as high as 49% for patients who have a long history of disease and who were less than 15 years of age at the time of diagnosis.

The inflammatory response seen in IBD has also been blamed for the systemic complications seen in both CD and UC. The systemic extraintestinal complications of UC are summarized in the next section.

**Hepatobiliary Complications**

Approximately 11% of patients with UC are reported to have hepatobiliary complications with overall frequencies ranging from 5% to 95% for patients with IBD. Hepatic complications include fatty liver, pericholangitis, chronic active hepatitis, and cirrhosis. Biliary complications include primary sclerosing cholangitis, cholangiocarcinoma, and gallstones.

Fatty infiltration of the liver may be a result of malabsorption, protein-losing enteropathy, or concomitant steroid use. The most common hepatic complication is pericholangitis (acute inflammation surrounding the intrahepatic portal venules, bile ducts, and lymphatics), which occurs in up to one third of UC patients. This is associated with progressive fibrosis of intrahepatic and extrahepatic bile ducts in a small percentage of UC patients and is referred to as primary sclerosing cholangitis. Cirrhosis may be a sequela of cholangitis or of chronic active hepatitis. Often the severity of hepatic disease does not correlate with gastrointestinal disease activity.

Gallstones occur commonly for patients with CD (particularly with terminal ileal disease) and may be related to bile salt malabsorption. In addition, cholangiocarcinoma occurs 10 to 20 times more frequently in IBD patients as compared with the general population.

**Joint Complications**

Arthritis commonly occurs in IBD patients and is typically asymmetric (unlike rheumatoid arthritis) and migratory, involving one or a few usually large joints. The joints most often affected are the knees, hips, ankles, wrists, and elbows in decreasing frequency. Sacroiliitis also occurs commonly. Arthritis associated with UC is generally related to the severity of colonic disease, and resolution without recurrence is seen with proctocolectomy. In addition, arthritis in this setting is different from rheumatoid arthritis in that rheumatoid factors are generally not detected. It is nondeforming and nondestructive, even after multiple episodes.

Another potential joint complication is ankylosing spondylitis, which is often unresponsive to treatment. The incidence of ankylosing spondylitis in patients with UC is 30 times that of the general population and occurs most commonly for patients with the HLA-B27 phenotype.

**Ocular Complications**

Ocular complications including iritis, uveitis, episcleritis, and conjunctivitis occur in up to 10% of patients with IBD. The most commonly reported symptoms with iritis and uveitis include blurred vision, eye pain, and photophobia. Episcleritis is associated with scleral injection, burning, and increased secretions. These complications may parallel the severity of intestinal disease, and recurrence after colectomy with UC is uncommon.

**Dermatologic and Mucosal Complications**

Skin and mucosal lesions associated with IBD include erythema nodosum, pyoderma gangrenosum, and aphthous ulceration. Five percent to 10% of IBD patients experience dermatologic or mucosal complications. Raised, red, tender nodules that vary in size from 1 cm to several centimeters are manifestations of erythema nodosum. They are typically found on the tibial surfaces of the legs and arms. These lesions are more commonly observed in CD patients and are noted to correlate with disease severity.

Pyoderma gangrenosum occurs more commonly for patients with UC (1% to 5% incidence) and is characterized by discrete skin ulcerations that have a necrotic center and a violaceous color of the surrounding skin. They can be seen on any part of the body but are more commonly found on the lower extremities.

Oral lesions are found in 6% to 20% of patients with CD and 8% of patients with UC. The most common lesion seen with CD is aphthous stomatitis. The severity of these lesions tends to parallel the disease course.

**CROHN’S DISEASE**

Crohn’s disease is best characterized as a transmural inflammatory process. The terminal ileum is the most common site of the disorder, but it may occur in any part of the GI tract from mouth to anus. About two thirds of patients have some colonic involvement, and 15% to 25% of patients have only colonic disease. Patients often have normal bowel separating segments of diseased bowel; that is, the disease is discontinuous.

Regardless of the site, bowel wall injury is extensive and the intestinal lumen is often narrowed. The mesentery first becomes thickened, edematous, and then fibrotic. Ulcers tend to be deep and elongated and extend along the longitudinal axis of the bowel, at least into the submucosa. The “cobblestone” appearance of the bowel wall results from deep mucosal ulceration intermingled with nodular submucosal thickening.

Complications of CD may involve the intestinal tract or organs unrelated to it. Small bowel stricture and subsequent obstruction is a complication that may require surgery. Fistula formation is common and occurs much more frequently than with UC. Fistulas often occur in the areas of worst inflammation, where loops of bowel have become matted together by fibrous adhesions. Fistulas may connect a segment of the GI tract to skin (enterocutaneous fistula), two segments of the GI tract (enteroenteric fistula), or the intestinal tract with the bladder (enterovesical fistula) or vagina. CD fistulae or abscesses associated with them frequently require surgical treatment.

Bleeding with CD is usually not as severe as with UC, although patients with CD may have hypochromic anemia. In addition, as with UC, the risk of carcinoma is increased but not as greatly as with UC.

Systemic complications of CD are common, and similar to those found with UC. Arthritis, iritis, skin lesions, and liver disease often accompany CD. Renal stones occur in up to 10% of patients with CD (less frequently with UC) and are caused by fat malabsorption, which allows for greater oxalate absorption and formation of calcium oxalate stones. Gallstones also occur with greater frequency in patients with UC, possibly because of bile acid malabsorption at the terminal ileum.

Nutritional deficiencies are common with CD. Reported frequencies of various nutritional parameters are weight loss, 40% to 80%; up to 90% reported in children at the time of diagnosis; growth failure in children, 15% to 88%; iron deficiency anemia, 39%; vitamin B12 deficiency, 18.4%; folate deficiency, 19%; hypocalcemia, 17% to 76%; hypokalemia, 33%; and osteomalacia, 36%. There are usually decreased fat stores and lean tissue. Growth failure in children may also be associated with hypozincemia.
Clinical Presentation of Ulcerative Colitis

Clinical Presentation of Crohn’s Disease

Although a typical clinical picture of UC can be described, there is a wide range of presentation, from mild abdominal cramping with frequent small-volume bowel movements to profuse diarrhea (Table 41–3). Most patients with UC experience intermittent bouts of illness after varying intervals with no symptoms. Only a small percentage of patients has continuous unremitting symptoms or a single acute attack with no subsequent symptoms.

Complex disease classifications are generally not used in clinical practice for UC. The arbitrarily determined distinctions of mild, moderate, and severe disease activity are generally used, and these are determined largely by clinical signs and symptoms.  

Mild: Fewer than 4 stools daily, with or without blood, with no systemic disturbance and a normal erythrocyte sedimentation rate (ESR).

Moderate: More than 4 stools per day but with minimal systemic disturbance.

Severe: More than 6 stools per day with blood, with evidence of systemic disturbance as shown by fever, tachycardia, anemia, or ESR of greater than 30 mm/h.

Fulminant: More than 10 bowel movements per day with continuous bleeding, toxicity, abdominal tenderness, requirement for transfusion, and colonic dilation.

It is also important to determine disease extent; that is, which part of the colon is involved—rectum, descending colon only, or the entire colon. Patients with “distal” disease have inflammation limited to areas distal to the splenic flexure (also referred to as left-sided disease), while those with “extensive disease” have inflammation extending proximal to the splenic flexure. Likewise, inflammation confined to the rectal area is referred to as proctitis, while disease involving the rectum and sigmoid colon is referred to as proctosigmoiditis. Inflammation of the majority of the colon is deemed pancolitis.

Two thirds of patients with UC have mild disease, which almost always starts in the rectum. Systemic signs and symptoms of the disease (e.g., arthritis, uveitis, or pyoderma gangrenosum) may be present in these patients and, in fact, may be the reason the patient seeks medical attention. Patients with mild disease are believed to be at lower risk of colon cancer. Moderate disease is observed in one fourth of patients.

With severe disease, the patient is usually found to be in acute distress, has profuse bloody diarrhea, and often has a high fever with leukocytosis and hypoalbuminemia. Often, the patient is dehydrated and therefore may be tachycardic and hypotensive. This presentation may have a sudden onset with rapid progression.

The diagnosis of UC is made on clinical suspicion and confirmed by biopsy, stool examinations, sigmoidoscopy or colonoscopy, or barium radiographic contrast studies. The presence of extracolonic manifestations such as arthritis, uveitis, and pyoderma gangrenosum may also aid in establishing the diagnosis.

CROHN’S DISEASE

As with UC, the presentation of CD is highly variable. A single episode may not be followed by further episodes, or the patient may experience continuous, unremitting disease. The time between the onset of complaints and the initial diagnosis may be as long as 3 years. The patient typically presents with diarrhea and abdominal pain. Hematochezia occurs in about one half of the patients with colonic involvement and much less frequently when there is no colonic involvement. Commonly, a patient may first present with a perirectal or perianal lesion (Table 41–4). The diagnosis should also be suspected in children with growth retardation, especially with abdominal complaints.

Much like UC, guidelines classify the severity of active CD by the presence of several signs and symptoms. Patients with mild to moderate CD are typically ambulatory and have no evidence of dehydration, systemic toxicity, loss of body weight, or abdominal tenderness, mass, or obstruction. Moderate to severe disease is considered for patients who fail to respond to treatment for mild to moderate disease or those with fever, weight loss, abdominal pain or tenderness, vomiting, intestinal obstruction, or significant anemia. Severe to fulminant CD is classified as the presence of persistent symptoms or evidence of systemic toxicity despite corticosteroid or biologic treatment or presence of cachexia, rebound tenderness, intestinal obstruction, or abscess. Disease activity may be assessed and correlated by evaluation serum C-reactive protein (CRP) concentrations.

The course of CD is characterized by periods of remission and exacerbation. Some patients may be free of symptoms for years, while others experience chronic problems in spite of medical therapy. As with UC, the diagnosis of CD involves a thorough evaluation using laboratory, endoscopic, and radiologic testing to detect the extent and characteristic features of the disease. Because of similarities that may exist between UC and CD confined to...
Inflammatory Bowel Disease

### TREATMENT

**Inflammatory Bowel Disease**

#### DESIRED OUTCOME

To treat IBD properly, the clinician must have a clear concept of realistic therapeutic goals for each patient. These goals may relate to resolution of acute inflammatory processes, resolution of attendant complications (e.g., fistulas and abscesses), alleviation of systemic manifestations (e.g., arthritis), maintenance of remission from acute inflammation, or surgical palliation or cure. Treatment goals and the approach to the therapeutic regimen differ considerably between UC and CD.

When determining goals of therapy and selecting therapeutic regimens, it is important to understand the natural history of IBD. Some cases of acute UC are self-limited. With mild to moderate acute colitis without systemic symptoms, 20% of patients may experience spontaneous improvement in their disease within a few weeks; however, a small percentage of patients may go on to experience more serious disease. With severe colitis, improvement without treatment cannot be expected. For instance, the response to medical management of toxic megacolon is variable and emergent colectomy may be required. When remission of UC is achieved, it is likely to last at least 1 year with medical therapy. In the absence of medical therapy, one half to two thirds of patients are likely to relapse within 9 months. In some reports, remission rates with placebo have approached those found with active treatment.

Since CD is typified by a chronic relapsing course, approximately 20% of patients with CD will experience a relapse annually. The chance of sustained remission is impacted by response to treatment. If patients remain in remission for 1 year, they have an 80% chance of remaining in remission the subsequent year, while 70% of patients will continue to have active disease in the year following a 12-month period in which they had active disease. Thus inducing and maintaining remission for patients with IBD is an important aspect of treatment.

#### GENERAL APPROACH TO TREATMENT

Treatment of IBD centers on agents used to relieve the inflammatory process. Aminosalicylates, corticosteroids, antimicrobials, immunosuppressive agents, such as azathioprine, mercaptopurine, and methotrexate, and biologic agents are commonly used to treat active disease and for some agents to lengthen the time of disease remission. Information regarding the extent and distribution of the disease should be taken into account, as this will often dictate the route and formulation of drug therapy that will be most effective.

In addition to the use of drugs, surgical procedures are sometimes performed when active disease is inadequately controlled or when the required drug dosages pose an unacceptable risk of adverse effects. For most patients with IBD, nutritional considerations are also important because these patients are often malnourished. Finally, a variety of therapies may be used to address complications or symptoms of IBD. For example, antidiarrheals may be used in some patients with relatively well-controlled disease, although these are generally to be avoided in active moderate to severe UC because they may contribute to the development of toxic colonic dilatation. Antimicrobial agents may be used in conjunction with drainage when abscesses are present or for patients with perianal disease. Iron supplementation may be required, particularly with UC, where blood loss from the colon can be significant.

#### NONPHARMACOLOGIC THERAPY

**Nutritional Support**

Proper nutritional support is an important aspect of the treatment of patients with IBD, not because specific types of diets are useful in alleviating the inflammatory conditions but because patients with moderate to severe disease are often malnourished, either because the inflammatory process results in significant malabsorption or maldigestion or because of the catabolic effects of the disease process. Elevated levels of interleukin-6 and TNF-α are known to increase protein turnover, resulting in protein loss and muscle wasting. Malabsorption may occur in the patient with CD with inflammatory involvement of the small bowel, where many nutrients are absorbed, as well as in patients who have undergone multiple small bowel resections with subsequent reduction in absorptive surface (“short gut”). Maldigestion with accompanying diarrhea can occur if there is a bile salt deficiency in the gut.

Many specific diets have been tried to improve the condition of patients with IBD, but none has gained widespread acceptance. With each individual it may be helpful to eliminate specific foods that exacerbate symptoms. This elimination process must be conducted cautiously, as patients have been known to exclude a wide range of nutritious products without adequate justification. Some patients with IBD, although not the majority, have lactase deficiency; therefore, diarrhea may be associated with milk intake. For these patients, avoidance of milk or supplementation with lactase generally improves the patient’s symptoms. Patients with small bowel strictures due to CD should avoid excessive high-residue foods, such as citrus fruits and nuts.

The nutritional needs of the majority of patients can be adequately addressed with enteral supplementation. In severe acute UC, enteral nutrition resulted in a significantly greater increase in serum albumin, fewer adverse effects related to the nutritional regimen, and fewer postoperative infections, as compared with isocaloric, isonitrogenous parenteral nutrition. The regimens were similar with regard to remission rate and the need for colectomy. Consideration should be given to lipid administration for its caloric value, as well as in recognition of depleted peripheral fat stores in many IBD patients and the greater potential for fatty acid deficiency. The use of enteral nutrition for patients with CD is preferable, as favorable effects on modulation of proinflammatory cytokine production may lead to enhanced maintenance of nutritional stores and increased growth rates in children. Likewise, use of enteral nutrition may facilitate induction of remission in up to 60% of patients with active CD and possibly reduce the use of corticosteroids.

Parenteral nutrition may be used in the treatment of severe CD or UC. The use of parenteral nutrition allows complete bowel rest for patients with severe UC, which may alter the need for proctocolectomy. Parenteral nutrition has also been valuable in CD since remission may be achieved with parenteral nutrition in about 50% of patients. In some patients, the disease may worsen when parenteral nutrition is stopped. Patients who have severe CD may require a course of parenteral nutrition to attain a reasonable nutritional status or in preparation for surgery, as poor perioperative nutritional status is associated with an increased incidence of postoperative complications. Patients with enterocutaneous fistulas of various etiologies benefit from parenteral nutrition.

Parenteral nutrition may also be valuable in children or adolescents with growth retardation associated with CD, but surgery is often
necessary with severe disease. Home parenteral nutrition may be required for patients requiring long-term therapy, particularly those with “short gut” as a consequence of surgical resection. Lastly, parenteral nutrition is more costly and is associated with more complications, such as serious infections, compared with enteral nutrition. Therefore, use should be limited to those patients for whom enteral nutrition is not preferred or feasible.

There is a growing interest in using probiotic approaches for IBD. Probiotics may lead to reestablishment of normal bacterial flora within the gut by oral administration of live bacteria such as nonpathogenic Escherichia coli, bifidobacteria, lactobacilli, or Streptococcus thermophilus. Probiotic formulations have been effective in maintaining remission in some trials for patients with UC; however differences in methodology, probiotics used, and underlying treatments for IBD make comparison of trials difficult.46–48 A formulation of Bifidobacterium, Lactobacilli, and Streptococci (VSL #3) is marketed specifically for use in UC as an adjunctive therapy and for patients who have a surgically constructed ileal pouch to prevent pouchitis.49 Review of evidence for the probiotic use in the induction and maintenance of CD has led to the recommendations not supporting widespread use, but rather further investigation.49–52

**Surgery**

Even with medical therapy 30% to 40% of patients with UC and 70% to 80% of patients with CD require surgical intervention at some point in their life.53 Although surgery (proctocolectomy) is curative for UC, this is not the case for CD. Surgical procedures involve resection of segments of intestine that are affected, as well as correction of complications (e.g., fistulas) or drainage of abscesses.

For UC, colectomy may be necessary when the patient has disease uncontrolled by maximum medical therapy or when there are complications of the disease such as colonic perforation, toxic dilatation (megacolon), uncontrolled colonic hemorrhage, or colonic strictures. Colectomy may be indicated for patients with long-standing disease (greater than 8 to 10 years), as a prophylactic measure against the development of cancer, and for patients with premalignant changes (severe dysplasia) on surveillance mucosal biopsies. The most common surgical procedures include proctocolectomy (after which the patient is left with a permanent ileostomy) and abdominal colectomy, with removal of the mucosa of the rectum and anastomosis of an ileal pouch to the anus (ileal pouch-anal anastomosis).54 The risk from surgery for these patients is relatively low if the operations are performed on a nonemergent basis.

The indications for surgery with CD are not as well established as for UC, and surgery is usually reserved for the complications of the disease. A recognized problem with intestinal resection for CD is the high rate of recurrence. Surgery may be appropriate in well-selected patients who have severe or incapacitating disease or obstruction in spite of aggressive medical management. The surgical procedures performed include resections of the major intestinal areas of involvement. For some patients with severe rectal or perianal disease, particularly abscesses, diversion of the fecal stream is performed with a colostomy. Other indications for surgery include strictures, colon cancer, an inflammatory mass, or intestinal perforations or fistulas.

**PHARMACOLOGIC THERAPY**

Drug therapy plays an integral part in the overall treatment of IBD. None of the drugs used for IBD are curative; at best, they serve to control the disease process. Therefore, a reasonable goal of drug therapy is resolution of disease symptoms such that the patient can carry on normal daily functions. The major types of drug therapy used in IBD include aminosalicylates, corticosteroids, immunosuppressive agents (azathioprine, mercaptopurine, cyclosporine, and methotrexate), antimicrobials (metronidazole and ciprofloxacin), and agents to inhibit TNF-α (anti-TNF-α antibodies) or leukocyte adhesion and migration (natalizumab).

Sulfasalazine, an agent that combines a sulfonamide (sulfapyridine) antibiotic and mesalamin (5-aminosalicylic acid) in the same molecule, has been used for many years to treat IBD but was originally intended to treat arthritis. Sulfasalazine is cleaved by gut bacteria in the colon to sulfapyridine (which is mostly absorbed and excreted in the urine) and mesalamine (which mostly remains in the colon and is excreted in stool).44–52–56

The active component of sulfasalazine is mesalamin, and the mechanism of action is not well understood.44–52–56 Cyclooxygenase or lipoxygenase inhibition alone does not entirely account for the agent’s effects. Aminosalicylates may block production of prostaglandins and leukotrienes, inhibit bacterial peptide-induced neutrophil chemotaxis and adenosine-induced secretion, scavenge reactive oxygen metabolites, and inhibit activation of the nuclear regulatory factor NF-κB.57 Sulfasalazine is often used initially before oral mesalamine derivatives when expense is an issue; however, it is not tolerated as well as the mesalamine alternatives.

Because the mechanism of action of sulfasalazine is not related to the sulfapyridine component and since sulfapyridine is believed to be responsible for many of the adverse reactions to sulfasalazine, mesalamin alone can be used. Mesalamin can be used topically as an enema or suppository for the treatment of proctitis or given orally in slow-release formulations that deliver mesalamin to the small intestine and colon (Table 41–5 and Fig. 41–1). Slow-release
Gastrointestinal Disorders

SECTION 4

Mesalamine suppository

Drug passing into the colon. A tablet formulation of mesalamine allows for once daily dosing.

Corticosteroids are widely used for the treatment of UC and CD, given parenterally, orally, or rectally. Corticosteroids modulate the immune system and inhibit production of cytokines and mediators. It is not clear whether the most important steroid effects are systemic or local (mucosal). Budesonide is a corticosteroid that is administered orally in a controlled-release formulation designed to release in the terminal ileum. The drug undergoes extensive first-pass metabolism; so systemic exposure is thought to be minimized. Immunosuppressive agents such as azathioprine, mercaptopurine, methotrexate, or cyclosporine are also used for the treatment of IBD (Table 41–6).

Azathioprine and mercaptopurine are effective for long-term treatment of both CD and UC. These agents are generally reserved for patients who are refractory to or dependent upon corticosteroids. They are usually used in conjunction with mesalazine derivatives and/or steroids and must be used for extended periods of time, ranging from a few weeks up to 12 months, before benefits may be observed. Early use of azathioprine in combination with infliximab for patients with CD who are naive to treatment with immunosuppressive agents or corticosteroids improves outcomes versus use of these agents individually.

Azathioprine and mercaptopurine may be associated with serious adverse effects such as lymphomas, pancreatitis, or nephrotoxicity. Predisposition to development of these adverse effects may be related to polymorphisms in the enzymes thiopurine methyl transferase (TPMT), which is partially responsible for activation and metabolism of these drugs. The Food and Drug Administration recommends that patients be tested for TPMT genotype and phenotype or activity prior to initiating therapy to identify patients that may have reduced TPMT activity and thus be at risk for toxicity. Adjusting azathioprine and mercaptopurine doses by measuring concentrations of metabolites, particularly 6-thioguanine (6-TGN), may be useful, with higher levels associated with greater remission rates.

Cyclosporine has also been of short-term benefit in treatment of acute, severe UC when used in a continuous intravenous infusion. Lower dose continuous infusions (2 mg/kg vs 4 mg/kg daily), or oral daily doses of 5 to 6 mg/kg in conjunction with steroids may be an effective option for those with fulminant disease. The agent poses a risk of nephrotoxicity and neurotoxicity. Some studies evaluating tacrolimus for the treatment of IBD suggest a potential role for use in patients with fistulizing CD, for patients unresponsive to steroids or infliximab, or in management of some extraintestinal manifestations. Methotrexate 25 mg given intramuscularly or subcutaneously once weekly is useful for treatment and maintenance of CD and may result in steroid sparing effects, while data supporting use in UC are lacking.

Antimicrobial agents, particularly metronidazole, are frequently used in attempts to control CD but are not typically useful in UC. Metronidazole is of value for some patients with active CD, particularly involving the perineal area or when fistulas or abscesses are present. Likewise, there may be a role for use of metronidazole in combination with azathioprine to reduce post-surgical recurrence of CD. The mechanism of metronidazole’s action involves inhibition of bacteria; so topical or intravenous administration is preferred for the perianal area. Other antimicrobial agents include fluoroquinolones, such as ciprofloxacin.

Inflammatory Bowel Disease
CHAPTER 41

Effect on CD has not been determined but is theorized to relate to interruption of a bacterial role in the inflammatory process. Ciprofloxacin has also been used for treatment of IBD, with some studies demonstrating efficacy for CD when used in combination with metronidazole. Rifaximin, a nonabsorbable antibiotic, has also shown some efficacy in treatment of both UC and CD.

Three biologic agents are now available for treatment of IBD that target TNF-α. Infliximab is an IgG1 chimeric monoclonal antibody that is administered intravenously and binds TNF-α and inhibits its inflammatory effect in the gut. The agent is useful for moderate to severe active CD and UC disease, as well steroid-dependent or fistulizing disease, as both an induction and maintenance therapy. Adalimumab is also an IgG1 antibody to TNF-α; however, this agent, unlike infliximab, is fully humanized and contains no murine sequences. Theoretically, the lack of a murine component in adalimumab reduces antibody development seen with use of infliximab. This agent can be administered subcutaneously. Adalimumab is a treatment option for patients with moderate to severe active CD previously treated with infliximab who have lost response. Certolizumab pegol is a humanized pegylated Fab fragment directed against TNF-α that is administered subcutaneously and demonstrates similar efficacy to adalimumab and infliximab.

Lastly, natalizumab is a novel biologic agent that inhibits leukocyte adhesion and migration by targeting α4 integrin. This agent can be used in the treatment of CD for patients who are unresponsive to other therapies, including corticosteroids and TNF-α inhibitors.

Ulcerative Colitis

Mild to Moderate Disease Most patients with active UC that have mild to moderate disease can be managed on an outpatient basis with oral or topical (rectal) therapies (Fig. 41–2, Table 41–7). The first line of drug therapy for patients with extensive disease is oral sulfasalazine or an oral mesalamine derivative. Topical mesalamine in an enema or suppository formulation is more effective than oral mesalamine or topical steroids for distal disease. The combination of oral and topical mesalamine is more effective than either alone for active distal disease. When given orally, usually 4 to 6 g/day, and possibly up to 8 g/day, of sulfasalazine is required to attain control of active inflammation. There does not appear to be an increased rate of response with increased dosage over 6 g/day, although side effects increase. Even with the use of adequate doses, patient improvement usually takes 4 weeks and sometimes longer. The dosage of sulfasalazine that can be given is usually limited by the patient’s tolerance of the agent; most adverse effects of sulfasalazine are dose related (GI disturbances, headache, and arthralgia).

Sulfasalazine therapy should be instituted at 500 mg/day and increased every few days up to 4 g/day or the maximum tolerated. It should not be used for patients with allergy to sulfonamide-containing drugs.

FIGURE 41-2. Treatment approaches for ulcerative colitis.
Oral mesalamine derivatives (such as those listed in Table 41–5) are reasonable alternatives to sulfasalazine for treatment of mild to moderate UC. Oral mesalamine products are used for patients with extensive disease, while topical agents, such as enemas and suppositories, are used for distal disease. Mesalamine is more effective than placebo but no more effective than sulfasalazine for treatment of mild to moderate UC, however, 15% to 25% of patients taking sulfasalazine experience severe diarrhea, often necessitating discontinuation of the drug. This results from a direct osmotic effect of the drug to induce small bowel fluid secretion. For this reason it is not the drug of first choice. Balsalazide is effective for treatment of mild to moderate UC. The new once daily formulations of mesalamine offer similar efficacy in mild to moderate UC with the benefit of once daily dosing and potentially lower pill burden. When used topically, mesalamine suppositories will only reach to the splenic flexure and therefore should be reserved for patients with proctitis. Enema formulations will reach to the splenic flexure and therefore can be used for distal disease.

Severe or Fulminant Disease

Systemic corticosteroids have a place in the treatment of moderate to severe active UC regardless of disease location or of those patients who are unresponsive to maximal doses of oral and/or topical mesalamine derivatives. Oral steroids (usually up to 1 mg/kg per day of prednisone equivalent or 40 to 60 mg daily) may be used for patients who do not have an adequate response to sulfasalazine or mesalamine. The response to steroids may be evident sooner than sulfasalazine or the aminosalicylates. Oral steroids should not be used as initial therapy for mild to moderate UC, mainly because of the known risks of steroid use. If steroids are used to attain remission, tapered drug withdrawal should be accomplished to minimize long-term steroid exposure. Topically administered steroids given as suppositories, enemas, or foams can be used as initial therapy for patients with ulcerative proctitis or distal colitis. Topical agents are also beneficial for treatment of tenesmus. With these agents, local actions are believed to be responsible for drug effects. Topical steroids are effective in the treatment of active, distal UC. However, rectal mesalamine is more effective than rectal steroids for inducing remission.

Infliximab is another viable option for patients with moderate to severe active UC who are unresponsive to steroids or other immunosuppressive agents. For outpatients with moderately active UC, infliximab demonstrated response rates of up to 69% at 8 weeks following initial doses of 5 mg/kg. Studies in hospitalized patients have shown mixed results, with some demonstrating reduced rates of colectomy for patients receiving infliximab.

Nicotine has been proposed as a treatment for UC (but not as a treatment for CD) based on the observation of the onset of a flare of UC after smoking cessation in some individuals. While less effective than aminosalicylates, transdermal nicotine in daily doses of 15 to 25 mg may improve symptoms for patients with mild to moderate UC, particularly for patients who are ex-smokers, and can be considered as an adjunctive therapy in both distal and extensive disease.

Severe or Fulminant Disease

Patients with uncontrolled severe colitis or who have incapacitating symptoms require hospitalization for effective management. Under these conditions, patients generally receive nothing by mouth to put the bowel at rest. Most medication is given by the parenteral route. Sulfasalazine or mesalamine derivatives are not beneficial for treatment of severe colitis because of rapid elimination of these agents from the colon with diarrhea, thereby not allowing sufficient time for gut bacteria to cleave the molecules. It is difficult to evaluate drugs in this setting, because patients with severe disease almost always receive additional medications including steroids.

Steroids have been valuable in the treatment of severe disease because the use of these agents may allow some patients to avoid colectomy. Intravenous hydrocortisone 300 to 400 mg daily in three divided doses or methylprednisolone 48 to 60 mg once daily are considered first-line agents. Methylprednisolone is typically preferred due to its lesser mineralocorticoid effects. A trial of steroids is warranted in most patients before proceeding to colectomy, unless the condition is grave or rapidly deteriorating. The length of the medical trial before consideration of surgery is open to debate. Steroids increase surgical risk, particularly infectious risk, if an operation is required later. After a colectomy is performed, steroids should no longer be required for the disease; however, they must be withdrawn gradually (usually over 3 to 4 weeks) to avoid hypoadrenal crisis due to adrenal suppression.

Patients who are unresponsive to parenteral corticosteroids after 7 to 10 days should receive cyclosporine by intravenous infusion. Seventy percent to 80% of hospitalized patients who are unresponsive to corticosteroids will respond to cyclosporine. Continuous intravenous infusion of cyclosporine (4 mg/kg per day) is typically effective in steroid-resistant acute severe UC and may reduce the need for emergent colectomy. Intravenous cyclosporine has also been recommended as an alternative to steroids for patients with severe attacks of UC (fulminant colitis). Patients who are controlled on intravenous cyclosporine can then be switched to an oral cyclosporine taper regimen with subsequent transition to azathioprine or mercaptopurine. As mentioned earlier, infliximab is also an alternative to cyclosporine and may also deter the need for colectomy for patients with severe disease not responsive to steroids.

Maintenance of Remission

After remission from active disease is achieved, the goal of therapy is to then maintain remission. The major agents used for maintenance of remission are sulfasalazine and the mesalamine derivatives. The value of sulfasalazine in preventing recurrences has been documented in several placebo-controlled trials. Sulfasalazine, most commonly dosed at 2 g/day, was superior to mesalamine when using the main end point of failure to maintain endoscopic or clinical remission. Sulfasalazine also appears to be more effective in maintaining remission compared with the newer agents, such as olsalazine.

For patients with distal disease or proctitis, mesalamine enemas or suppositories are considered first-line agents. The frequency of administration of topical agents may possibly be lessened to every third night over time. Oral agents, including sulfasalazine, mesalamine, and balsalazide, are also effective options if patients do not wish to use topical preparations. The combination of topical and oral mesalamine is superior to either regimen alone for maintenance therapy.

Clinical Controversy

A major question about the use of aminosalicylates for maintenance of remission of UC is whether they reduce the patient’s risk of developing colorectal cancer. It has been suggested that mesalamine, in doses >1.2 g/day, is protective against the development of colorectal cancer; however, this is not entirely supported by controlled trials. Given the often slow development of colorectal cancer and the relapsing nature of UC, these significantly limit the ability to conduct long-term surveillance studies for patients in remission.

Steroids do not have a role in the maintenance of remission with UC because they are ineffective. Steroids should be gradually withdrawn after remission is induced (over 3 to 4 weeks). If they are continued, the patient will be at risk for steroid-induced adverse effects without likelihood of benefits. For patients who require chronic steroid use (steroid dependency), there is a strong justification for alternative therapies or colectomy. Azathioprine is effective in preventing relapse of UC for periods exceeding 4 years. However, 3 to 6 months may be required before beneficial effects are noted. For patients who initially respond to infliximab, continued dosing of 5 mg/kg as maintenance therapy every 8 weeks is another alternative for corticosteroid-dependent patients or those failing immunosuppressive therapy.

Crohn’s Disease

Management of CD often proves more difficult than management of UC, partly because of the greater complexity of presentation with
CD (Fig. 41–3, Table 41–6). The disease may involve any segment of the GI tract, from mouth to anus, and may involve other visceral structures and soft tissues through fistulization. There is a greater reliance on drug therapy with CD because resection of all involved intestine may not be possible. Unfortunately, recurrence of CD is common following surgery with reported rates of up to 64% recurrence following surgical resection of affected areas of bowel.

**Mild to Moderate Active Crohn’s Disease**

The goal of treatment for active CD is to achieve remission; however, in many patients, reduction of symptoms so the patient may carry out normal activities or reduction of the steroid dose required for control is a significant accomplishment. In the majority of patients, mild to moderate active CD is treated with sulfasalazine or mesalamine derivatives, while steroids, azathioprine, mercaptopurine, methotrexate, biologic agents, or metronidazole are frequently considered first-line therapies for moderate to severe active CD and thus are not recommended for routine use.

Sulfasalazine, when administered in daily doses of 3 to 6 g, is slightly superior to placebo for patients with mild to moderate CD and is more effective when CD involves the colon. Mesalazine formulations such as Pentasa or Asacol have the ability to release mesalamine in the small bowel thus targeting ileal disease, yet have demonstrated variable results for patients with active CD. Only a few small trials utilizing Asacol at 3.8 g/day or Pentasa at 4 g/day have demonstrated superiority to placebo for treatment of active CD. Despite variable effectiveness, the mesalamine derivatives may be better tolerated than sulfasalazine, particularly at higher doses. Thus, a trial of sulfasalazine or an oral mesalamine derivative is reasonable as initial therapy for patients with mild to moderate active CD with ileal, ileocolonic, or colonic involvement.

Systemic corticosteroids are frequently used for the treatment of active CD, particularly with more moderate to severe presentations; however, controlled release budesonide (Entocort) is a viable first-line option for patients with mild to moderate ileal or right-sided (ascending colonic) disease. This agent is superior to placebo and has demonstrated superiority to mesalamine and reported rates of remission rates of up 69% at 8 weeks in some trials.

For this reason, recent guidelines advocate use of budesonide 9 mg/day as a first-line option for patients with CD confined to the ileum and/or right colon. Metronidazole (given orally up to 20 mg/kg per day in divided doses) has demonstrated variable efficacy but may possibly be useful in some patients with CD, particularly for patients with colonic or ileocolonic involvement or for those patients with perineal disease. For most patients with colonic or perianal disease, metronidazole would be added to a mesalamine product or steroids as adjunctive therapy, where satisfactory control of CD is not gained with first-line agents, or in attempts to reduce steroid dosage. Ciprofloxacin 1 g/day has gained attention as an alternative to metronidazole and has demonstrated some efficacy in small trials only. The combination of ciprofloxacin with metronidazole appears to be efficacious in some patients with perianal disease. Antibiotics demonstrate minimal efficacy in mild to moderate active CD and thus are not recommended for routine use.

**Moderate to Severe Active Crohn’s Disease**

Oral systemic steroids, such as prednisone 60 mg/day, are generally considered first-line therapies for moderate to severe active CD and are effective in inducing remission for up to 70% of patients. Oral systemic steroids should be reserved for patients with moderate to severe disease who have failed aminosalicylates or budesonide. Hospitalized patients with severe or fulminant disease or those who are unable to tolerate oral therapy are candidates for administration of parenteral steroids. Systemic steroids do not appear to be effective for treatment of perianal fistulas. The immunomodulators (azathioprine and mercaptopurine) are effective in maintaining steroid-induced remission and are generally limited to use for patients not achieving adequate response to standard medical therapy or to reduce steroid doses when high steroid doses are required. Azathioprine and mercaptopurine have both demonstrated long-term benefits for patients with CD. The usual doses of azathioprine is 2 to 3 mg/kg per day, and for mercaptopurine to 1.5 mg/kg per day. Starting doses are typically 50 mg/day and increased at 2-week intervals; however,
complete blood counts with differential should be monitored every 2 weeks while doses are being titrated. The onset of therapeutic effects are delayed with both azathioprine and mercaptopurine, and a minimum of 3 to 4 months is often required to see clinical benefits.

As mentioned previously, clinical response to mercaptopurine may be related to whole-blood concentrations of the metabolite 6-TGN, while toxicity is correlated with concentrations of another metabolite, 6-methylmercaptopurine. Determination of TPMT activity is recommended to determine which patients require lower doses of these agents. Alternatively, a newer strategy for evaluating a patient’s risk for toxicity is to perform a TPMT genotype or phenotype. This is recommended prior to therapy with subsequent dose adjustments based on the patient’s genotypic profile.

**CLINICAL CONTROVERSY**

While thiopurines, such as azathioprine and mercaptopurine, are effective for maintenance of remission of CD, it is debated how long treatment should be continued once remission is achieved. Evidence has demonstrated efficacy of these agents in maintaining remission for greater than 4 years; however, some authors argue that long-term exposure to these potentially toxic agents outweighs the benefit.

Although mostly used in the setting of maintenance therapy, methotrexate is another option for use as induction therapy for patients with moderate to severe CD. Use of a weekly intramuscular or subcutaneous injection of 25 mg has demonstrated efficacy for induction of remission in CD and has also demonstrated corticosteroid-sparing effects. While there are risks of bone marrow suppression, hepatotoxicity, and pulmonary toxicity, use of low-dose methotrexate appears relatively safe when continued as maintenance therapy if proper monitoring is implemented.

Infliximab is a well-established treatment option for moderate to severe active CD for patients failing immunosuppressive therapy, in those who are corticosteroid dependent, and for treatment of fistulizing disease. In large trials, a 5 mg/kg single intravenous infusion of infliximab resulted in clinical improvement in 58% of patients at 2 weeks and 65% of patients at 8 weeks. Continued dosing of 5 mg/kg at 2 and 6 weeks following the initial dose leads to higher response rates and is recommended as the regimen of choice for induction therapy in active disease. Response rates of up to 62% in the reduction of number of draining fistulas have been reported following induction therapy and continued maintenance dosing with infliximab. Patients who receive infliximab often develop antibodies to infliximab (ATI), which can result in increases in the occurrence of serious infusion reactions and loss of response to the drug. Up to 10% of patients per year require discontinuation of infliximab due to adverse effects and loss of efficacy related to development of ATIs. Strategies to reduce ATI formation include administration of a second dose within 8 weeks of the first dose, concurrent administration of steroids (hydrocortisone 200 mg intravenously on the day of the infusion or oral prednisone the day prior), and use of concomitant immunosuppressive agents. Induction of tolerance utilizing a dose escalation technique was also effective in administering infliximab to patients with previous severe infusion reactions. As mentioned previously, use of infliximab in combination with azathioprine may lead to better outcomes in steroid or immunosuppressive naïve patients.

Adalimumab is another viable option for moderate to severe CD. Trials evaluating treatment with adalimumab for patients with moderately to severely active CD who have lost response to infliximab have demonstrated up to a 54% complete response in some instances. Cetuximab has also demonstrated efficacy in moderate to severe CD with patients who have a baseline CRP of greater than 10 mg/dL exhibiting the best response rates, reported as 37% at 6 weeks versus 26% for placebo. Natalizumab is reserved for patients who do not respond to steroids or the TNF-α inhibitors. Patients who initially respond to natalizumab treatment had rates of sustained response reported as 61% versus 28% for placebo at week 36.

Cyclosporine is typically not recommended for treatment of CD except for acute management of patients with severe fistulizing disease. Up to 83% of patients with refractory fistulas responded to intravenous cyclosporine (4 mg/kg per day) within a mean of 7.9 days. The dose of cyclosporine is important in determining efficacy. An oral dose of 5 mg/kg per day is ineffective, whereas 7.6 mg/kg per day has demonstrated effectiveness in some trials. However, toxic effects limit the routine use of this higher dosage. At present, the therapeutic blood or plasma concentration range for cyclosporine has not been established for CD, but whole-blood trough concentrations of 300 to 500 ng/mL for intravenous therapy or 200 to 400 ng/mL for oral therapy have been established. When using cyclosporine clinicians should recognize the accompanying long-term risk of renal toxicity and infection, as well as the potential for drug interactions.

**Maintenance of Remission**

Prevention of recurrence of disease is typically more difficult with CD than with UC. There is minimal evidence to support that sulfasalazine and oral mesalamine derivatives are effective therapies for maintenance of CD following medically-induced remission. Despite these findings, an attempt to maintain remission with sulfasalazine and oral mesalamine following a medically-induced remission is reasonable given the favorable side-effect profile and cost of these drugs compared with the immunosuppressive and biologic agents. Mesalamine does appear to have some efficacy in preventing post surgical relapse following resection, with absolute risk reductions of 10% to 15% for relapse reported in some studies.

Systemic steroids have no place in the prevention of recurrence of CD. These agents do not appear to alter the long-term course of the disease and predispose patients to serious adverse effects with long-term use. Budesonide at maintenance doses of 6 mg/day has demonstrated efficacy in maintaining remission at 3 months; however, use longer than this is generally not recommended, as a loss of efficacy is seen after this time frame. Despite this recommendation, use of budesonide as maintenance therapy for up to 1 year results in low rates of clinically important adverse effects.

Azathioprine, mercaptopurine, and methotrexate are useful for some patients with CD to maintain remission. Azathioprine and mercaptopurine are effective in maintaining remission in CD for up to 4 years, particularly in steroid-induced remission, and therefore these drugs are generally considered first-line agents. Patients who may benefit from these agents include those with quiescent disease who are steroid dependent or refractory, in postsurgical patients to prevent recurrence, those with frequent flares requiring steroids, and those patients with perianal or enteric fistulas. For patients who initially respond to methotrexate, continued dosing at 15 mg intramuscularly once weekly is also effective in maintaining remission. This agent has steroid sparing effects and thus represents an alternative therapy to azathioprine and mercaptopurine.

Infliximab infusion given at a dose of 5 mg/kg every 8 weeks is more effective than placebo in maintaining remission for patients who initially respond to infliximab for active CD. An increase in the dose to 10 mg/kg is possible if loss of efficacy over
time is evident. Additionally, infliximab is the effective maintenance therapy for fistulizing disease; however, given the high cost of this agent, some have questioned whether this approach is the most cost effective.5 Adalimumab is also a treatment option for maintenance therapy of CD. Following induction therapy, doses of 40 mg subcutaneously every other week have resulted in clinical remission rates of 36% to 46% after 56 weeks of therapy.108,109 Certolizumab is also effective for maintenance of CD, with remission rates for patients who initially responded reported as 49% at 26 weeks versus 29% with placebo.97,110 For patients treated with natalizumab who initially respond, maintenance therapy led to response rates of 44% compared with 26% for placebo (P = 0.001).100

**CLINICAL CONTROVERSY**

Use of immunomodulator agents, such as azathioprine and mercaptopurine, is becoming more common earlier in the course of IBD and for patients who may not fully respond to aminosalicylates. For patients that are receiving aminosalicylates who are started on immunomodulator agents it is unclear as to whether the aminosalicylate should be continued once the immunomodulator becomes effective. Continued use of aminosalicylates may aid in prevention of colorectal cancer; however, the effects of continued use on disease control drug toxicity and adherence to therapy are not known.111

**SELECTED COMPLICATIONS**

**TOXIC MEGACOLON**

The treatment required for toxic megacolon includes general supportive measures to maintain vital functions, consideration for early surgical intervention, and use of drugs (steroids, cyclosporine, and antimicrobials).35,39 Aggressive fluid and electrolyte management is required for dehydration. Fluids and electrolytes may be lost through vomiting, diarrhea, and nasogastric intubation, as well as through fluid accumulation in the bowel. If the patient has lost significant amounts of blood, transfusion may be necessary. Opiates and medications with anticholinergic properties should be discontinued because these agents enhance colonic dilatation, thereby increasing the risk of bowel perforation. Broad spectrum antimicrobials that include coverage for gram-negative bacilli and intestinal anaerobes should be used as preemptive therapy in the event that perforation occurs.31 Fortunately, perforation occurs in only 2% to 3% of cases.39 If the patient is not on steroids, then high doses intravenous therapy should be administered to reduce acute inflammation. Emergent surgical intervention, mainly an abdominal colectomy with formation of an ileostomy, is an important consideration for patients with toxic megacolon and prevents death in some patients.31,39,53

**SYSTEMIC MANIFESTATIONS**

The common systemic manifestations of IBD include arthritis, anemia, and skin manifestations such as erythema nodosum and pyoderma gangrenosum, uveitis, and liver disease. These problems may be related to the inflammatory process. For some of these manifestations specific therapies can be instituted, whereas for others the treatment that is used for the GI inflammatory process also addresses the systemic manifestations.

Anemia occurs when there is significant blood loss from the GI tract. If the patient can consume oral medication, ferrous sulfate should be administered. If the patient is unable to take oral medication and the patient’s hematocrit is sufficiently low, blood transfusions or intravenous iron infusions may be required.34,35 Anemia may also be related to malabsorption of vitamin B12 or folic acid, particularly for patients who have had ileal resection, so these may also be required. Patients with IBD are also at high risk for bone loss, osteoporosis, and fractures.35,112 Screening for osteoporosis via DXA is recommended for patients using steroids for >3 months, in postmenopausal females, males over age 50, and those who have sustained a low-stress fracture.53,112 If the patient is deemed high risk for osteoporosis, vitamin D and calcium should be instituted. If osteoporosis is present, then calcium, vitamin D, and a bisphosphonate are recommended.35,112 Corticosteroid use should be limited, and weight-bearing exercise initiated.

There are no consistently recommended therapies for apthous ulcers, liver disease, episcleritis, or uveitis associated with IBD. These manifestations are worse during exacerbations of the intestinal disease, and measures improving intestinal disease will improve these systemic manifestations. Unfortunately, this association has not been demonstrated consistently. For arthritis associated with IBD, aspirin or another NSAID may be beneficial, as might be steroids. However NSAID use may exacerbate the underlying IBD. Liver transplantation is being used more frequently for definitive treatment of primary sclerosing cholangitis. Infliximab and the other TNF-α inhibitors may alleviate some arthritic and skin manifestations of IBD such as anklylosing spondylitis, erythema nodosum, and pyoderma gangrenosum.35,113

**SPECIAL CONSIDERATIONS**

**PREGNANCY**

Either the occurrence or consideration of pregnancy may cause significant concerns for the patient with IBD. Patients with IBD have similar infertility rates as the general female population, thus the rate of normal childbirth is similar to that for healthy populations.114–116 Some studies have noted a greater risk of spontaneous abortions for patients with IBD. Furthermore, there is a greater incidence of low-birth-weight infants for mothers with chronic idiopathic UC.114 Pregnancy has minimal effects on the course of IBD.114–116 Likewise, IBD appears to have little effect on the course of pregnancy, particularly if the IBD is quiescent at the time of conception.114–116 Patients who are pregnant experience IBD recurrence rates similar to those of nonpregnant females. In addition, there is no justification for therapeutic abortion with IBD because termination of the pregnancy has not been observed to improve the disease.

Steroids and sulfasalazine may be administered during pregnancy with the same guidelines that would be applied to the non-pregnant patient.114–116 Steroids given systemically do not appear to be detrimental to the fetus. Sulfasalazine is generally well tolerated; however, it does interfere with folate absorption, so supplementation with folic acid 1 mg twice daily should be used during the pregnancy.114 Interestingly, sulfasalazine causes decreased sperm counts and reduced fertility in males.114 This effect is reversible on discontinuation of the drug, and it is not reported with mesalamine. Immunosuppressive drugs (azathioprine and mercaptopurine) may be associated with fetal deformities in humans and are classified as pregnancy category D; however, they have been used commonly in IBD without detriment for most patients.114–116 Infliximab, adalimumab, and certolizumab are classified as pregnancy category B drugs and appear to be relatively safe for use in pregnant patients.114–116 Natalizumab is a pregnancy category C drug, and thus
may be used if benefit is thought to outweigh risk. Metronidazole may be used for short courses for treatment of trichomoni-asis, but prolonged use should be avoided due to potential mutagenic effects. Methotrexate should not be used during pregnancy, as it is a known abortifacient (category X). Although prednisone and prednisolone can be detected in breast milk, breast-feeding is believed to be safe for the infant when low doses of prednisones are used. Sulfasalazine does not pose a risk of kernicterus, as levels of sulfapyridine in breast milk are low or undetectable. Metronidazole should not be given to nursing mothers because it is excreted into breast milk.

**ADVERSE DRUG EFFECTS**

Drug intolerance often limits the usefulness of agents used to treat IBD. Many patients receiving sulfasalazine, mesalamine, corticosteroids, metronidazole, azathioprine, mercaptopurine, methotrexate, or biologic agents may experience undesired effects. In some cases, these adverse effects can be significant and require discontinuation of the therapy. Knowledge of the common or important adverse reactions will assist in avoiding or minimizing their effects.

Sulfasalazine is often associated with adverse drug effects, and these effects may be classified as either dose related or idiosyn- cratic. The sulfapyridine portion of the sulfasalazine molecule is believed to be responsible for much of the sulfasalazine toxicity. Dose-related side effects usually include GI disturbances such as nausea, vomiting, diarrhea, or anorexia but may also include headache and arthralgia. These adverse reactions tend to occur more commonly on initiation of therapy and decrease in frequency as therapy is continued. Approaches to the management of these adverse effects include discontinuing the agent for a short period and then reintroducing the agent at a reduced dosage with subsequent slower dose escalation, administration with food, or substituting another enteric-coated 5-ASA product. Folic acid absorption is impaired by sulfasalazine, which may lead to anemia. Patients receiving sulfasalazine should receive oral folic acid supplementation.

Adverse effects that are idiosyncratic are not dose related and most commonly include rash, fever, or hepatotoxicity, as well as relatively uncommon but serious reactions such as bone marrow suppression, thrombocytopenia, pancreatitis, pneumonitis, interstitial nephritis, and hepatitis. For most patients with idiosyncratic reactions, sulfasalazine must be discontinued. In some patients who have experienced allergic reactions to sulfasalazine, a desensitization procedure can be instituted. By gradually increasing sulfasalazine dosage over weeks to months, patient tolerance has been improved.

Oral mesalamine derivatives may impose a lower frequency of adverse effects as compared with sulfasalazine. Up to 80% to 90% of patients who are intolerant to sulfasalazine will tolerate oral mesalamine derivatives. However, olsalazine may cause watery diarrhea in up to 25% of patients, often requiring drug discontinuation.

Adverse reactions to corticosteroids are well recognized and may occur when corticosteroids are used for any indication. However, there is a greater potential for adverse effects when corticosteroids are used for the treatment of IBD because high doses must often be used for extended periods. The well-appreciated adverse effects of corticosteroids include hyperglycemia, hypertension, osteoporosis, acne, fluid retention, electrolyte disturbances, myopathies, muscle wasting, increased appetite, psychosis, and reduced resistance to infection. In addition, corticosteroid use may cause adrenocortical suppression. To minimize corticosteroid effects, clinicians have used alternate-day steroid therapy; however, some patients do not do well clinically on the days when no steroid is given. For most patients a single daily corticosteroid dose suffices, and divided daily doses are unnecessary. Another problem with corticosteroids is adrenal insufficiency after abrupt steroid withdrawal. This necessitates gradual tapering of steroid therapy for patients using these agents daily for more than 2 to 3 weeks. Due to its lower bioavailability and lower potential for adverse effects, budesonide may be used as alternate steroid therapy in CD involving the ileum or right colon or may be substituted for prednisone in CD patients who are steroid dependent or require long-term therapy.

Immunomodulators, such as azathioprine and mercaptopurine, have a significant potential for adverse reactions and have resulted in withdrawal rates in clinical trials of up to 20%. Adverse events to thiopurines are typically divided into two groups, type A and type B. Type A are dose related and include malaise, nausea, infectious complications, hepatitis, and myelosuppression. As mentioned earlier, the myelosuppression from azathioprine and mercaptopurine is related to a deficiency of TPMT with subsequent accumulation of toxic metabolites. Type B reactions are considered idiosynractic and include fever, rash, arthralgia, and pancreatitis (3% to 15% of patients). Mercaptopurine causes adverse reactions similar to azathioprine; however, there are fewer reports of lymphomas with this agent. Some data suggest that mercaptopurine may be used successfully for patients who are intolerant to azathioprine.

Most patients receiving metronidazole for CD tolerate the agent fairly well; however, mild adverse effects occur frequently. They commonly include nausea, metallic taste, urticaria, and glossi-tis. More serious effects that occur with long-term use include development of paresthesias and reversible peripheral neuropathy. Other effects include a disulfiram-like reaction if alcohol is ingested in conjunction.

The TNF-α inhibitors may be associated with development of serious adverse effects and carry similar adverse profiles for the available agents. Infliximab use has been associated with infusion reactions. Premedication with acetaminophen, diphenhydramine, and possibly corticosteroids may reduce the incidence and severity of these reactions. Due to administration via the subcutaneous route, adalimumab and certolizumab may be more associated with injection site reactions versus infusion-related reactions. Serum sickness has occurred for patients who received infliximab doses separated by a long period of time. Infliximab autoimmunity phenomena, such as lupus and hemolytic anemia, may also occur during infliximab therapy, as well as an increase in the incidence of adverse neurologic events such as optic neuritis and demyelinating syndrome. Risk of hepatosplenic T-cell lymphoma may be increased with use of infliximab, particularly if used in combination with immunomodulators such as azathioprine. Young male patients appear to be at higher risk for development of lymphoma.

Infliximab may also cause worsening of heart failure and thus is contraindicated for patients with New York Heart Association Class III or IV heart failure. All TNF-α inhibitors predispose patients to development of serious infections. Patients with clinically significant active infections should not receive TNF-α inhibitors. Sepsis and tuberculosis may occur because of the inhibition of TNF-protective mechanisms. Patients should receive a tuberculin skin test [purified protein derivative (PPD)] ORA QuantiFERON® test and a chest x-ray prior to initiating therapy to rule out undiagnosed tuberculosis. Reactivation of hepatitis B may occur; thus, patients should also be screened for hepatitis B virus infection prior to initiating therapy. Patients should also be screened for hepatitis C infection, although it does not appear that use of TNF-α inhibitors alter the disease course. Patients receiving natalizumab is associated with development of progressive multifocal leukoencephalopathy and is only available via the manufacturer’s TOUCH prescribing program. Patients receiving...
nontalizumab should be monitored for development of adverse neurologic events and undergo MRI of the brain should development of progressive multifocal leukoencephalopathy be suspected.

**EVALUATION OF THERAPEUTIC OUTCOMES**

The success of therapeutic regimens to treat IBD can be measured by patient-reported complaints, signs, and symptoms; by direct clinician examination (including endoscopy); by history and physical examination; by selected laboratory tests; and by quality-of-life measures. Evaluation of IBD severity is difficult because much of the assessment is subjective. To create more objective measures, disease rating scales or indices have been created. The CD Activity Index (CDAI) is a commonly used scale, particularly for evaluation of patients during clinical trials. The scale incorporates eight elements: (1) number of stools in the past 7 days, (2) sum of abdominal pain ratings from the past 7 days, (3) rating of general well-being in the past 7 days, (4) use of antidiarrheals, (5) body weight, (6) hematocrit, (7) finding of abdominal mass, and (8) a sum of extraintestinal symptoms present in the past week. Elements of this index provide a guide for those measures that may be useful in assessing the effectiveness of treatment regimens. A subsequent scale was developed specifically for Perianal CD, known as the Perianal CD Activity Index (PDAI). The PDAI includes five items: presence of discharge, pain, restriction of sexual activity, type of perianal disease, and degree of induration.

Standardized assessment tools have also been constructed for UC. Elements in these scales include (1) stool frequency, (2) presence of blood in the stool, (3) mucosal appearance (from endoscopy), and (4) physician’s global assessment based on physical examination, endoscopy, and laboratory data. Additional studies that are often useful include direct endoscopic examination of affected areas and/or radiocontrast studies. For patients with acute disease, assessment of fluid and electrolyte status is important, because these may be lost during diarrheal episodes. Other laboratory tests, such as serum albumin, transferrin, or other markers of visceral protein status as well as markers of inflammation (ESR or CRP), may be used.

Assessment of the IBD patient must include consideration of adverse drug effects. Because many of the agents used have a relatively high probability of causing adverse effects, particularly corticosteroids and other immunosuppressive agents, patient assessment should include collection of history and physical and laboratory data that are necessary to prevent or recognize adverse drug effects.

Finally, a patient quality-of-life assessment should be performed regularly. Agents that appear clinically equivalent may differ substantially in resulting quality of life. Inquiry should be made regarding general well-being, emotional function, and social function. Social function may include assessment of the ability to perform routine daily functions and to maintain occupational activities, sexual function, and recreation. The most common tool used to assess quality of life is the Inflammatory Bowel Disease Questionnaire (IBDQ), a 32-item questionnaire that covers four disease dimensions: bowel function, emotional status, systemic symptoms, and social function. The IBDQ has shown good correlation with the CDAI. A shortened version has also been developed for use in the community practice setting. A lesser used tool is the Rating Form of Inflammatory Bowel Disease Patient Concerns.

Quality-of-life studies have been conducted with infliximab. To balance the exceptionally high cost of this therapy, CD patients who receive infliximab have improved quality of life, have fewer emergency room visits, have a reduced requirement for surgery, and are more likely to be employed.

Nausea and Vomiting

CHAPTER 42

KEY CONCEPTS

1. Nausea and/or vomiting is often a part of the symptom complex for a variety of gastrointestinal, cardiovascular, infectious, neurologic, metabolic, or psychogenic processes.

2. Nausea or vomiting is caused by a variety of medications or other noxious agents.

3. The overall goal of treatment should be to prevent or eliminate nausea and vomiting regardless of etiology.

4. Treatment options for nausea and vomiting include drug and nondrug modalities such as relaxation, biofeedback, and self-hypnosis.

5. The primary goal with chemotherapy-induced nausea and vomiting (CINV) is to prevent nausea and/or vomiting. Optimal control of acute nausea and vomiting positively impacts the incidence and control of delayed and anticipatory nausea and vomiting.

6. The primary goal of chemotherapy-induced nausea and vomiting (CINV) is to prevent nausea and/or vomiting. Optimal control of acute nausea and vomiting positively impacts the incidence and control of delayed and anticipatory nausea and vomiting.

7. Patients at high risk of vomiting should receive prophylactic antiemetics for postoperative nausea and vomiting.

8. Patients receiving single-exposure, high-dose radiation therapy to the upper abdomen or receiving total or hemibody irradiation, should receive prophylactic antiemetics for radiation-induced nausea and vomiting.

Nausea and vomiting are common complaints in individuals of all ages. Disorders are discussed in Etiology section. However, because of the variable etiologies of these problems, management can be quite simple or detailed and complex, essentially innocuous or associated with therapy-induced adverse reactions. This chapter provides an overview of nausea and vomiting, two multifaceted problems.

Nausea is usually defined as the inclination to vomit or as a feeling in the throat or epigastric region alerting an individual that vomiting is imminent. Vomiting is defined as the ejection or expulsion of gastric contents through the mouth and is often a forceful event. Either condition may occur transiently with no other associated signs or symptoms; however, these conditions also may be only part of a more complex clinical presentation.

ETIOLOGY

1. Nausea and vomiting may be associated with a variety of conditions, including gastrointestinal (GI), cardiovascular, infectious, neurologic, or metabolic disease processes. Nausea and vomiting may be a feature of such conditions as pregnancy, or may follow operative procedures or administration of certain medications, such as those used in cancer chemotherapy. Psychogenic etiologies of these symptoms may be present, especially in young women with an underlying emotional disturbance. Anticipatory etiologies may be involved, such as in patients who have previously received cytotoxic chemotherapy. Table 42–1 lists specific etiologies associated with nausea and vomiting.1

   The etiology of nausea and vomiting may vary with the age of the patient. For example, vomiting in the newborn during the first day of life suggests upper digestive tract obstruction or an increase in intracranial pressure. Other illnesses associated with vomiting in children include pyloric stenosis, duodenal ulcer, stress ulcer, adrenal insufficiency, septicemia, and diseases of the pancreas, liver, or biliary tree. 2 Drug-induced nausea and vomiting are of particular concern, especially with the increasing number of patients receiving cytotoxic treatment. A four-level classification system defines the risk for emesis with specific cytotoxic agents (Table 42–2).2 Although some agents may have greater emetic risk than others, combinations of agents, high doses, clinical settings, psychological conditions, prior treatment experiences, and unusual stimulus of sight, smell, or taste may alter a patient’s response to drug treatment. In this setting, nausea and vomiting may be unavoidable and some patients experience these problems so intensely that chemotherapy is postponed or discontinued.

Cancer patients undergoing chemotherapy may experience breakthrough nausea and/or vomiting despite receiving prophylactic antiemetics. Historically, breakthrough emesis occurs in 10% to 40% treated with modern-day antiemetics. Anticipatory nausea or vomiting (ANV) is believed to be a learned, conditioned, or psychological response to a poor outcome from a previous event. It may be triggered by tastes, odors, sights, thoughts, or anxiety associated with chemotherapy. 3 In the setting of optimal antiemetic prophylaxis, chemotherapy-induced ANV can occur in up to 10% and 20% of patients receiving chemotherapy but rarely occurs unless the patient has previously experienced post-treatment nausea or vomiting.4, 5 In addition to the emetic risk of various cytotoxic regimens, other common etiologies have been proposed for the development of nausea and vomiting in cancer patients (Table 42–3).6, 7

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.
The three consecutive phases of emesis include nausea, retching, and vomiting. Nausea, the imminent need to vomit, is associated with gastric stasis and may be considered a separate and singular symptom. Retching is the labored movement of abdominal and thoracic muscles before vomiting. The final phase of emesis is vomiting, the forceful expulsion of gastric contents caused by GI retroperistalsis. The act of vomiting requires the coordinated contractions of the abdominal muscles, pylorus, and antrum, a raised gastric cardia, diminished lower esophageal sphincter pressure, and esophageal dilatation. Vomiting should not be confused with regurgitation, an act in which the gastric or esophageal contents rise to the pharynx because of pressure differences caused by, for example, an incompetent lower esophageal sphincter. Accompanying autonomic symptoms of pallor, tachycardia, and diaphoresis account for many of the distressing feelings associated with emesis.

Vomiting is triggered by afferent impulses to the vomiting center, a nucleus of cells in the medulla. Impulses are received from sensory centers, which include the chemoreceptor trigger zone (CTZ), cerebral cortex, and visceral afferents from the pharynx and GI tract. These afferent impulses are integrated by the vomiting center, resulting in efferent impulses to the salivation center, respiratory center, and the pharyngeal, GI, and abdominal muscles, leading to vomiting.

CHAPTER 42

Presentation of Nausea and Vomiting

Nonchemotherapy Etiologies of Nausea and Vomiting

The CTZ, located in the area postrema of the fourth ventricle of the brain, is a major chemosensory organ for emesis and is usually associated with chemically induced vomiting. Because of its location, bloodborne and cerebrospinal fluid toxins have easy access to the CTZ. Therefore, cytotoxic agents primarily stimulate this area rather than the cerebral cortex and visceral afferents. Similarly, pregnancy-associated vomiting probably occurs through stimulation of the CTZ.

Numerous neurotransmitter receptors are located in the vomiting center, CTZ, and GI tract, including cholinergic, histaminic, dopaminergic, opiate, serotonergic, neurokinin, and benzodiazepine receptors. Chemotherapeutic agents, their metabolites, or other emetic compounds theoretically trigger the process of emesis through stimulation of one or more of these receptors. Effective antiemetics are able to antagonize or block the emetogenic receptors.

CLINICAL PRESENTATION

Because it is impossible to discuss all clinical settings in which the presence of nausea and vomiting might be a pertinent finding, these processes are presented in Table 42-4 as they might occur together, and also as simple or complex in presentation.

TREATMENT

■ DESIRED OUTCOME

The overall goal of antiemetic therapy is to prevent or eliminate nausea and vomiting. This should be accomplished without adverse effects or with clinically acceptable adverse effects. Although this goal may be accomplished easily in patients with simple nausea and vomiting, patients with more complex problems require greater assistance. In addition to these clinical goals, appropriate cost issues should be considered, particularly in the management of chemotherapy-induced and postoperative nausea and vomiting.

■ GENERAL APPROACH TO TREATMENT

Treatment options for nausea and vomiting include drug and nondrug modalities. The treatment of nausea and vomiting is quite varied depending on the associated medical situation. Even though a number of potentially effective measures are available, most patients receive a medication at some point in their care. For simple nausea and vomiting, patients may choose to do nothing or to select from a variety of nonprescription drugs. As symptoms become worse or are associated with more serious medical problems, patients are more likely to benefit from prescription antiemetic drugs. When prescribed according to reliable clinical information, these agents often provide acceptable relief; however, some patients will never be totally free of symptoms. This lack of relief is most disabling when it is associated with an unresolved medical problem or when the necessary therapy for this condition is the cause of the nausea or vomiting, as in the case of patients who are receiving chemotherapy of moderate or high emetic risk.

■ NONPHARMACOLOGIC MANAGEMENT

Nonpharmacologic management of nausea and vomiting involves the use of a variety of dietary, physical, or psychological strategies that are consistent with the etiology of nausea and vomiting. For patients with simple complaints, perhaps resulting from excessive or disagreeable food or beverage consumption, avoidance or moderation in dietary intake may be preferable. Patients suffering symptoms of systemic illness may improve dramatically as their underlying condition resolves. Finally, patients in whom these symptoms result from labyrinthine changes produced by motion may benefit quickly by assuming a stable physical position.

Nonpharmacologic interventions are classified as behavioral interventions and include relaxation, biofeedback, self-hypnosis, cognitive distraction, guided imagery, acupuncture, and systematic desensitization.9,10 The reader is referred to references 11 to 13 for a more complete discussion on nonpharmaceutical strategies.

■ PHARMACOLOGIC THERAPY

Although many approaches to the treatment of nausea and vomiting have been suggested, antiemetic drugs (nonprescription and prescription) are most often recommended. These agents represent a variety of pharmacologic and chemical classes, as well as dosage regimens and routes of administration. With so many treatment possibilities available, factors that enable the clinician to

discriminate among various choices include (a) the suspected etiology of the symptoms; (b) the frequency, duration, and severity of the episodes; (c) the ability of the patient to use oral, rectal, injectable, or transdermal medications; and (d) the success of previous antiemetic medications. Please see Table 42–5 for dosing information of commonly available antiemetic preparations.

The treatment of simple nausea and vomiting usually requires minimal therapy. For these symptoms, patients may choose from a lengthy list of nonprescription products. Both nonprescription and prescription drugs useful in the treatment of simple nausea and vomiting are usually effective in small, infrequently administered doses. Side effects and toxic effects in these settings are also usually minimal. Although suitable for occasional simple nausea and vomiting, nonprescription agents are often abandoned by the patient as symptoms continue or become progressively worse. As the patient’s condition warrants, prescription medications may be chosen, either as single-agent therapy or in combination.

The management of complex nausea and vomiting, for example, in patients who are receiving cytotoxic chemotherapy, may require combination therapy. In combination regimens, the goal is to achieve symptomatic control through administration of agents with different pharmacologic mechanisms of action.

### Antacids

Patients who are experiencing simple nausea and vomiting may use various antacids. In this setting, single or combination nonprescription antacid products, especially those containing magnesium hydroxide, aluminum hydroxide, and/or calcium carbonate, may provide sufficient relief, primarily through gastric acid neutralization.

Common antacid regimens for the relief of acute or intermittent nausea and vomiting include one or more 15 to 30 mL doses of single- or multiple-agent products. Potential adverse effects from antacids are usually related to the presence of magnesium, aluminum, or calcium salts. Specifically, osmotic diarrhea from magnesium and constipation from aluminum or calcium salts may be of concern to patients, particularly those self-medicating with

high or frequently administered antacid doses. Generally, however, when used occasionally for acute episodic relief of nausea and vomiting, antacids do not produce serious toxicities.

**Antihistamine–Anticholinergic Drugs**

Antiemetic drugs from the antihistaminic–anticholinergic category appear to interrupt various visceral afferent pathways that stimulate nausea and vomiting and may be appropriate in the treatment of simple nausea and vomiting. Adverse reactions associated with the use of the antihistaminic–anticholinergic agents primarily include drowsiness, confusion, blurred vision, dry mouth, and urinary retention, and possibly tachycardia, particularly in elderly patients. Also, as doses are increased or are more frequently administered, patients with narrow-angle glaucoma, prostatic hyperplasia, or asthma are at greater risk of complications from the anticholinergic effects of these drugs.

**Benzodiazepines**

Since nausea and vomiting are often associated with chemotherapy, radiotherapy, and surgery, anticipatory anxiety may occur prior to these therapies and may exacerbate symptoms. Benzodiazepines may be useful in this setting.

Benzodiazepines are relatively weak antiemetics and are primarily used to prevent anxiety or ANV in patients receiving highly emetogenic chemotherapy. They are also useful as adjuncts to other antiemetics in patients treated with cisplatin-containing regimens. Lorazepam significantly reduced the incidence of ANV in cisplatin-treated patients. Lorazepam caused both mild sedation and amnesia. Alprazolam is usually given orally and has an onset of about 60 minutes, while lorazepam is given orally or sublingually, which has a more rapid onset.

**Buterophenones**

Two buterophenone compounds that have antiemetic activity are haloperidol and its congener droperidol; both block dopaminergic stimulation of the CTZ. Although each agent is effective in relieving nausea and vomiting, haloperidol is not considered first-line therapy for uncomplicated nausea and vomiting but has been used in palliative care situations. The current labeling of droperidol recommends that all patients should undergo a 12-lead electrocardiogram prior to administration, followed by cardiac monitoring for 2 to 3 hours after administration because of the possibility of the development of potentially fatal QT prolongation and/or torsade de pointes. The clinical use of droperidol has effectively ceased outside of clinical trials in anesthesia.

**Cannabinoids**

Cannabinoids have complex effects on the central nervous system (CNS) and their effects at receptors in neural tissues may explain efficacy in chemotherapy-induced nausea and vomiting (CINV). Oral dronabinol and nabilone are one of several therapeutic options when CINV is refractory to other antiemetics; they are not indicated as first-line agents.

Chemotherapy use with over 1,300 patients in 30 randomized, controlled trials from 1975 to 1996 was analyzed to quantify the antiemetic efficacy and adverse effects of several cannabinoids. Oral nabilone, oral dronabinol, and intramuscular levonantradol were compared with conventional antiemetics (prochlorperazine, metoclopramide, chlorpromazine, thiemyprazine, haloperidol, domperidone, and alizapride) or placebo. Across all trials, cannabinoids were slightly more effective than active comparators and placebo when the chemotherapy regimen was of moderate emetogenic potential, and patients preferred them. No dose–response relationships were evident to the authors. Side effects included euphoria, drowsiness, sedation, somnolence, dysphoria, depression, hallucinations, and paranoia.

**Corticosteroids**

Corticosteroids have demonstrated antiemetic efficacy since the initial recognition that patients who received prednisone as part of their Hodgkin disease protocol appeared to develop less nausea and vomiting than did those patients who were treated with protocols that excluded this agent. Methylprednisolone has also been used as a component of an antiemetic regimen, but the majority of trials have included dexamethasone. The site and mechanism of action of corticosteroids for CINV is unknown.

Dexamethasone is the most commonly used corticosteroid in the management of chemotherapy-induced and postoperative nausea and vomiting (PONV), either as a single agent or in combination with 5-hydroxytryptamine-3 receptor antagonists (5-HT₃-RA). For CINV, dexamethasone is effective in the prevention of both cisplatin-induced acute emesis and when used alone or in combination for the prevention of delayed nausea and vomiting associated with CINV, 18–21. Corticosteroids affect almost every organ system. Insomnia, gastrointestinal symptoms, agitation, and appetite stimulation are some of the more common side effects reported in this patient population. For patients with simple nausea and vomiting, steroids are not indicated and may be associated with unacceptable risks.

**H₂-Receptor Antagonists**

Histamine₂-receptor antagonists work by decreasing gastric acid production and are used to manage simple nausea and vomiting associated with heartburn or gastroesophageal reflux. Except for potential drug interactions with cimetidine, these agents cause few side effects when used for episodic relief.

**5-Hydroxytryptamine-3 Receptor Antagonists**

5-HT₃-RAAs block presynaptic serotonin receptors on sensory vagal fibers in the gut wall, effectively blocking the acute phase of CINV. These agents do not completely block the acute phase of CINV and are less efficacious in preventing the delayed phase, but they are the standard of care in the management of CINV, PONV, and radiation-induced nausea and vomiting (RINV). Issues involved in the use of dolasetron, granisetron, ondansetron, and palonosetron are reviewed in detail in the sections that follow. The most common side effects associated with these agents are constipation, headache, and asthma.

**Metoclopramide**

Metoclopramide, a procainamide congener, provides significant antiemetic effects by blocking the dopaminergic receptors centrally in the CTZ. Metoclopramide increases lower esophageal sphincter tone, aids gastric emptying, and accelerates transit through the small bowel, possibly through the release of acetylcholine. Metoclopramide is used for its antiemetic properties in patients with diabetic gastroparesis and with dexamethasone for prophylaxis of delayed CINV. Its use as prophylaxis for acute chemotherapy-induced nausea and vomiting was supplanted by the introduction of the 5-HT₃-RAAs in the early 1990s. These agents have greater efficacy and decreased toxicity compared with metoclopramide in patients who are receiving cisplatin-based regimens. 22,23

**Olanzapine**

Olanzapine is an antipsychotic that blocks several neurotransmitters including dopamine at D₂ and 5-HT₃-RA. Use of olanzapine,
in combination with palonosetron and dexamethasone, effectively prevented acute CINV, while continued monotherapy with olanzapine prevented most cases of delayed nausea and vomiting in patients receiving moderately and highly emetogenic chemotherapy in a single-arm, phase 2 clinical trial in 40 patients. The National Comprehensive Cancer Network (NCCN) antiemesis practice guideline includes olanzapine as one of many options in patients who experience breakthrough nausea and/or vomiting following prophylaxis for CINV. Sedation is the most common side effect with olanzapine.

**Phenothiazines**

Phenothiazines have been the most widely prescribed antiemetic agents and appear to block dopamine receptors, most likely in the CTZ. Phenothiazines are marketed in an array of dosage forms, none of which appears to be more efficacious than another. These agents may be most practical for long-term treatment and are inexpensive in comparison with newer drugs. Rectal administration is a reasonable alternative in patients in whom oral or parenteral administration is not feasible.

Phenothiazines are most useful in adult patients with simple nausea and vomiting. Intravenous prochlorperazine provided quicker and more complete relief with less drowsiness than intravenous promethazine in adult patients treated in an emergency department for nausea and vomiting associated with uncomplicated gastritis or gastroenteritis. There are numerous potential side effects with these medications, including extrapyramidal reactions, hypersensitivity reactions with possible liver dysfunction, bone marrow aplasia, and excessive sedation.

**Substance P/Neurokinin 1 Receptor Antagonists**

Substance P is a peptide neurotransmitter in the neurokinin (NK) family whose preferred receptor is the NK, receptor. The acute phase of CINV is believed to be mediated by both serotonin and substance P, whereas substance P is believed to be the primary mediator of the delayed phase. Aprepitant is the first substance P/NK, receptor antagonist in clinical use; others are in development. The efficacy of aprepitant was demonstrated in patients receiving high-dose cisplatin-based chemotherapy and in patients receiving doxorubicin and cyclophosphamide, a regimen of moderate to high emetic risk. The three-drug regimen of aprepitant, dexamethasone, and ondansetron provided improved protection from vomiting for the 5 days after chemotherapy administration as compared with the combination of dexamethasone and ondansetron.

Aprepitant has the potential for numerous drug interactions because it is a substrate, moderate inhibitor, and an inducer of cytochrome isoenzyme CYP3A4 and an inducer of CYP2C9. Aprepitant can increase serum concentrations of many drugs metabolized by CYP3A4, including doxetaxel, paclitaxel, etoposide, irinotecan, ifosfamide, imatinib, vinorelbine, vincristine, and vinblastine. In clinical studies, aprepitant was concomitantly administered with etoposide, vinorelbine, or paclitaxel, with no adjustment in the doses of these agents to account for potential drug interactions. The efficacy of oral contraceptives may be reduced when given with aprepitant. Concomitant administration with warfarin may result in a clinically significant decrease in the international normalized ratio. The dose of oral dexamethasone should be reduced 50% when coadministered with aprepitant, because of the 2.2-fold increase in observed area under the plasma-concentration-versus-time curve. Aprepitant is not approved for use in children.

Fosaprepitant, an injectable form of aprepitant, has been approved by the FDA as an intravenous substitute for oral aprepitant on day 1 of the standard 3-day CINV prevention regimen, with oral aprepitant administered on days 2 and 3.

**Chemotherapy-Induced Nausea and Vomiting**

There are five categories of CINV: acute, delayed, anticipatory, breakthrough, and refractory. Nausea and vomiting that occurs within 24 hours of chemotherapy administration is defined as acute, whereas when it starts more than 24 hours after chemotherapy administration, it is defined as delayed. The primary goal with CINV is to prevent nausea and/or vomiting. Optimal control of acute nausea and vomiting impacts positively on the incidence and control of delayed and anticipatory nausea and vomiting.

Emesis occurring during previous chemotherapy predisposes for the risk of developing ANV. Breakthrough nausea and vomiting is defined as emesis occurring despite prophylactic administration of antiemetics, requiring use of rescue antiemetics. Poor response to multiple antiemetic regimens is defined as refractory nausea and vomiting.

Clinical practice guidelines for the use of antiemetics in CINV have been published. Despite the demonstrated improvement in outcomes with the use of these practice guidelines, they are underutilized by a high percentage of practitioners. Furthermore, product availability and recommended doses are often institution-specific and may vary considerably from the doses listed in Table 42–6.

Factors to consider when selecting an antiemetic for CINV include the following:

- The emetic risk of the chemotherapy agent or regimen (see Table 42–2)
- Patient-specific factors
- Patterns of emesis after administration of specific chemotherapy agents or regimens

**Prophylaxis of Acute CINV**

The emetic risk of the chemotherapeutic agent (see Table 42–2) is the primary factor to consider when deciding whether to administer prophylactic agents and which antiemetic(s) to select. Table 42–6 summarizes recommendations from version 4 of the 2009 NCCN antiemetic guidelines. Antiemetic guidelines published by other groups are in overall agreement with the NCCN guidelines.

Patients receiving chemotherapy that is classified as being of high emetic risk should receive a combination of three antiemetic drugs on the day of chemotherapy administration (day 1) including a 5-HT₃-RA (e.g., dolaprazin, granisetron, ondansetron, or palonosetron) + dexamethasone + an NK, receptor antagonist (e.g., aprepitant). Patients receiving regimens that are classified as moderate emetic risk should receive a two-drug combination antiemetic regimen containing a 5-HT₃-RA + dexamethasone on day 1. The exception to this is patients who are receiving an anthracycline plus cyclophosphamide and select patients receiving other chemotherapies of moderate emetic risk, for example, carboplatin, cisplatin, doxorubicin, epirubicin, ifosfamide, irinotecan or methotrexate; these patients should receive the triple-drug combination described for regimens of high emetic risk.

For chemotherapy regimens that are low emetic risk, dexamethasone or any of the following: prochlorperazine, metoclopramide, and/or diphenhydramine, and/or lorazepam alone is recommended for prophylaxis. When equivalent doses are used for the prevention of acute emesis, all 5-HT₃-RAs are considered to be of

CINV, chemotherapy-induced nausea and vomiting.

equivalent efficacy and safety. When available in both oral and intravenous dosage forms, oral agents are equally effective as intravenous products. The decision as to which 5-HT₃-RA to use should be based on patient-specific factors and cost.

Prophylaxis of Delayed CINV

Management of delayed CINV has historically challenged practitioners. The best strategy for preventing delayed CINV (nausea and/or vomiting occurring 24 or more hours after chemotherapy) is to control acute CINV and provide adequate prophylaxis for delayed CINV.²⁵ Aprepitant, dexamethasone, and metoclopramide are effective in preventing delayed CINV, whereas 5-HT₃-RA are inconsistent.²⁷ However, palonosetron controlled delayed emesis more effectively than granisetron, suggesting that another 5-HT₃-RA should not be prescribed as a rescue medication when palonosetron is given prophylactically for acute CINV.²⁶

Patients receiving cisplatin and other agents are at highest risk for experiencing delayed CINV. The addition of aprepitant in the recommended three-drug combination on the day of cisplatin administration and additional doses of aprepitant and dexamethasone on days two and three after cisplatin administration improved the control of delayed vomiting as compared with patients who received dexamethasone alone postchemotherapy (51% vs 72%).²⁰,²¹ Use of aprepitant also decreased delayed CINV in patients receiving an anthracycline plus cyclophosphamide, as compared with twice-daily ondansetron (49% vs 55%).²⁸ Current practice guidelines recommend administration of aprepitant and dexamethasone on days 2 and 3 and dexamethasone with or without lorazepam on day 4.²⁵

The incidence of delayed CINV following chemotherapy with agents of moderate emetic risk is less well defined. The current NCCN recommendation is to give aprepitant or any of the following: dexamethasone, a 5-HT₃-RA, and/or lorazepam and/or a histamine-2 blocker or a proton pump inhibitor on days 2 and 3.²³ The American Society of Clinical Oncology (ASCO) and Multinational Association of Supportive Care in Cancer (MASCC) practice guidelines do not include aprepitant on days 2 and 3.

A second-generation 5-HT₃-RA, palonosetron, has a prolonged serum half-life and higher receptor binding affinity that may offer another option for prophylaxis of delayed CINV. Palonosetron given once every 7 days protected more patients from delayed emesis than either ondansetron or dolasetron in adult patients receiving chemotherapy of moderate emetic risk.²⁷–²⁹ Subsequently, a large randomized, blinded study in patients receiving chemotherapy of high emetic risk showed that palonosetron plus dexamethasone was not inferior to granisetron plus dexamethasone for controlling acute CINV but was superior for delayed CINV.³⁰ Palonosetron may also be better than ondansetron in patients receiving multi-day chemotherapy, but a larger randomized, prospective trial is needed to substantiate the finding of a recent study.³¹

Treatment of Anticipatory Nausea and Vomiting

ANV is more difficult to control than acute or delayed CINV. A key principle in the treatment of ANV is that effective management of delayed CINV or ANV requires adequate control of acute CINV.²⁴ In addition, ANV may be prevented with behavioral therapy or pharmacotherapy.²² The benzodiazepines, lorazepam and alprazolam, are effective in preventing ANV and improve outcomes in both acute and delayed emesis.

Treatment of Breakthrough CINV

Breakthrough nausea and/or vomiting occurs in 10% to 40% of patients receiving chemotherapy despite the use of multiagent prophylaxis.³² All patients receiving chemotherapy should be prescribed antiemetics for rescue of breakthrough nausea and vomiting. Rescue medications used in adult patients include prochlorperazine, promethazine, lorazepam, metoclopramide, haloperidol, benzodiazepines such as lorazepam, 5-HT₃-RAs, dexamethasone, and cannabinoids such as dronabinol or olanzapine.²³,²⁴

Around-the-clock dosing of rescue antiemetics should be considered rather than as-needed administration. The choice of agent should be based on patient-specific factors, including potential adverse drug reactions and cost. Chlorpromazine, lorazepam, and dexamethasone are recommended for pediatric patients.²⁴
Treatment of Refractory Nausea and Vomiting

The general approach to the management of refractory CINV is to upgrade the antiemetic strategy to the next level of prophylaxis or to add breakthrough antiemetics to the regimen.49 Some patients will experience nausea and vomiting despite optimal acute and delayed prophylaxis and failure of rescue antiemetics. Addition of another agent from a different pharmacologic class is recommended and routes other than the oral route may be required. Agents such as corticosteroids, haloperidol, olanzapine, and nabilone in alternating schedules or by alternating routes are recommended.55

Prophylaxis of Anticipatory Nausea and Vomiting

As stated earlier, ANV rarely occurs unless the patient has previously experienced post-treatment nausea or vomiting. ANV may also be prevented with prophylactic pharmacotherapy using benzodiazepines the night before and morning of chemotherapy. A large observational study done after the introduction of 5-HT\(_3\)-RAs in patients receiving granisetron as antiemetic therapy evaluated ANV as an outcome.7 An incidence of anticipatory nausea was observed in 10% and anticipatory vomiting in 2% of patients, which is substantially lower than reported prior to the application of effective antiemetic regimens.46

CLINICAL CONTROVERSY

The prevention of CINV in patients receiving multi-day chemotherapy is complicated by the overlap of acute and delayed emesis after the first day of chemotherapy. There are few studies and a lower complete control rate using standard antiemetic prophylaxis for patients receiving multi-day chemotherapy regimens.47 While acute emesis can be controlled adequately, delayed emesis occurs in 50% or more of patients. Agents such as palonosetron, aprepitant, dexamethasone, and olanzapine are effective for both acute and delayed emesis and may have the greatest potential for success in multiday chemotherapy regimens. While the latest NCCN guidelines provide suggestions in this setting, further research is necessary before definitive recommendations can be made.

POSTOPERATIVE Nausea AND VOMITING

Postoperative nausea and vomiting (PONV) in adults complicates surgical procedures for approximately 25% to 30% of patients undergoing anesthesia.48 PONV usually occurs within 24 hours after anesthesia, with the highest incidence during the first 2 hours. Most patients undergoing an operative procedure do not require preoperative prophylactic antiemetic therapy and universal PONV prophylaxis is not cost-effective. Table 42–7 summarizes the risk factors for PONV. The use of a risk assessment tool can improve emetic outcomes in patients undergoing surgery by identifying the patients most likely to benefit from prophylaxis.49

Adherence to consensus guidelines for prophylaxis and treatment of PONV decreases emetic episodes.50,51 In addition to using prophylactic antiemetics in high-risk patients, other strategies include using regional rather than systemic anesthesia, propofol, and hydration, as well as avoiding nitrous oxide, volatile anesthetics, and opioids. Total intravenous anesthesia reduced the risk of PONV similar to the prophylactic administration of a single antiemetic.52

Prophylaxis of PONV

The most important independent predictors for PONV are female, nonsmoking, a history of PONV or motion sickness, and use of postoperative opioids. A simplified risk model allows clinicians to estimate the risk for PONV among patient groups.49 Patients with 0 or 1 of these 4 risk factors present are at lowest risk (10–20%) and those with 3 or 4 risk factors are at highest risk for PONV (60–80%). Moderate risk is defined by this model as the presence of 2 risk factors. Although the optimal management of PONV is not known, patients at highest risk of vomiting should receive prophylactic antiemetics. Patients at low risk for PONV are unlikely to benefit from prophylaxis and may potentially experience adverse reactions from the medications.

Patients at moderate risk for PONV should receive one or two prophylactic antiemetics, and those at high risk should receive two prophylactic antiemetic agents from different classes.50,51 Optimal dosing of agents used in combination has not been determined. When the different combinations were compared, no differences were found between 5-HT\(_3\)-RA plus droperidol; 5-HT\(_3\)-RA plus dexamethasone; and droperidol plus dexamethasone.52

Cyclizine, dexamethasone, dolasetron, droperidol, granisetron, metoclopramide, ondansetron, tropisetron, scopolamine, and palonosetron are as effective as placebo for the prophylaxis of PONV.54–56 Table 42–8 summarizes the doses for prophylactic antiemetics from the consensus guidelines.50

Dexamethasone is an effective, inexpensive prophylactic agent when administered either alone or in combination with other antiemetic drugs before the induction of anesthesia.52,54,55 Although droperidol is one of the most effective agents for PONV prophylaxis, concerns about the development of torsade de pointes severely limit its use.56 With equivalent efficacy and safety profiles, acquisition cost was the primary factor that differentiated the 5-HT\(_3\)-RAs from each other.57 5-HT\(_3\)-RAs appear to be most effective when given at the end of surgery.

The NK\(_\alpha\) antagonist aprepitant was approved for the prevention of PONV at a dose of 40 mg given orally within 3 hours prior to induction of anesthesia.58 Aprepitant is equivalent to ondansetron 4 mg IV in the incidence of nausea and reducing the need for rescue in the 24 hours after surgery, but was significantly better than ondansetron for preventing vomiting in the 24 and 48 hours after surgery.59

**Treatment of PONV**

Patients who experience PONV after receiving prophylactic treatment with a 5-HT₃-RA plus dexamethasone should receive rescue therapy from a different drug class such as a phenothiazine, metoclopramide, or droperidol.46 Repeating the agent given for PONV prophylaxis within 6 hours of surgery is of no additional benefit.46 Furthermore, a repeated dose of a 5-HT₃-RA is not effective in treatment of PONV.61,62 An emetic episode occurring more than 6 hours postoperatively can be treated with any of the drugs used for prophylaxis except dexamethasone and transdermal scopolamine.60

If no prophylaxis was given, the recommended treatment is low-dose 5-HT₃-RA as follows: dolasetron 12.5 mg, granisetron 0.1 mg, ondansetron 1 mg, and tropisetron 0.5 mg. Alternative treatments for established PONV include dexamethasone 2 to 4 mg IV, droperidol 0.625 mg IV, or promethazine 6.25 to 12.5 mg IV.63

**RADIATION-INDUCED NAUSEA AND VOMITING (RINV)**

Nausea and vomiting associated with radiation therapy is not well understood. It is neither as predictable nor as severe as CINV, and many patients receiving radiation therapy will not experience nausea or vomiting. Risk factors associated with the development of RINV include the site of radiation, the dose, dose rate, and area of the body to be irradiated.

Patients receiving high-dose radiation therapy to the upper abdomen, or total or hemi-body irradiation, should receive prophylactic antiemetics for RINV.

**Prophylaxis of RINV**

Four radiotherapy-induced emesis risk groups have been defined by the Antiemetic Subcommittee of the MASCC and the ASCO antiemetic practice guidelines.43,63 Both groups recommend preventive therapy with a 5-HT₃-RA and dexamethasone in patients who are receiving total body irradiation (high emetic risk). The efficacy of oral granisetron 2 mg and ondansetron 8 mg was demonstrated in 34 patients who underwent hyperfractionated total body irradiation.64 Patients undergoing radiation therapy procedures with moderate to low emetic risk should receive a 5-HT₃-RA prior to each fraction.

---

**DISORDERS OF BALANCE**

Disorders of balance include vertigo, dizziness, and motion sickness. The etiology of these complaints may include diseases that are infectious, postinfectious, demyelinating, vascular, neoplastic, degenerative, traumatic, toxic, psychogenic, or idiopathic. Symptoms of imbalance perceived by the patient present a particular clinical challenge. Whether associated with a minor or complex disorder, motion sickness may be associated with nausea and vomiting.

Beneficial therapy for patients in this setting can most reliably be found among the antihistaminic–anticholinergic agents. However, the precise mechanisms of action of these agents are currently unknown. Neither the antihistaminic nor the anticholinergic potency appears to correlate well with the ability of these agents to prevent or treat the nausea and vomiting associated with motion sickness. When used for their depressant effects on labyrinth excitability, these agents produce variable efficacy and safety profiles. Oral regimens of antihistaminic–anticholinergic agents given one to several times each day may be effective, especially when the first dose is administered prior to motion.

Scopolamine is commonly used to prevent nausea or vomiting caused by motion. The usefulness of scopolamine in preventing motion sickness was enhanced with the development of the transdermal system (patch) that increased patient satisfaction and decreased untoward side effects. A review of 12 randomized, controlled studies showed that scopolamine provided better protection from motion-induced sickness than did placebo, but was not superior to antihistamines and combinations of scopolamine and ephedrine.65

**ANTIEMETIC USE DURING PREGNANCY**

As many as 75% of pregnant women experience nausea and vomiting to some degree during the first trimester of pregnancy. The severity of the symptoms varies considerably, from mild nausea to incapacitating nausea and vomiting. Severity may be decreased by taking a multiple vitamin at the time of conception. The etiology of nausea and vomiting of pregnancy (NVP) is not well understood. For the majority of women, these symptoms are self-limited, although approximately 1% to 3% develop hyperemesis gravidarum, a serious condition marked by severe physical symptoms and/or medical complications requiring hospitalization. In its most...
severe state, hyperemesis gravidarum may result in volume contraction, starvation, and electrolyte abnormalities.

Initial management of NVP often involves dietary changes and/or lifestyle modifications. Nonpharmacologic interventions for NVP include ginger and acupressure, although efficacy trials for acupressure are lacking. Persistent nausea and/or vomiting leads to the consideration of drug therapy at a time when teratogenic potential of each agent must be considered.

Treatment recommendations for the management of NVP are available from the American College of Obstetricians and Gynecologists (ACOG). A comprehensive review of treatment options for NVP was published. Pyridoxine (10–25 mg 1–4 times daily), without or without doxylamine (12.5–20 mg 1–4 times daily), is recommended as first-line therapy. In cases of refractory NVP, addition of a histamine 1-receptor antagonist such as dimenhydrinate (50–100 mg orally or rectally every 4–6 hours as needed), diphenhydramine (25–50 mg orally or 10–50 mg IV every 4–6 hours as needed), or meclizine (25 mg orally every 4–6 hours as needed) is recommended. Patients with persistent NVP or who show signs of dehydration should receive intravenous fluid replacement with thiamine. Ondansetron 2 to 8 mg orally/IV every 8 hours as needed may alleviate NVP, but intravenous ondansetron was no more effective than promethazine for treatment of severe NVP. Corticosteroids should be reserved for patients with refractory NVP or hyperemesis gravidarum; methylprednisolone 16 mg orally/IV every 8 hours for 3 days followed by a 2-week taper is recommended. This regimen may be repeated if necessary, but treatment should not exceed a total of 6 weeks.

**ANTIEMETIC USE IN CHILDREN**

**CINV**

Practice guidelines recommend that a corticosteroid (such as dexamethasone) plus a 5-HT3-RA be administered to children receiving chemotherapy of high or moderate emetic risk. Although studies show there is a wide variation in metabolism and clearance of 5-HT3-RAs, higher weight-based doses have not been adequately studied in pediatric patients.

Consensus guidelines suggest that there are no differences between 5-HT3-RAs in safety or efficacy. However, a randomized, comparative study demonstrated that one dose of palonosetron 0.25 mg IV provided better complete control than ondansetron (8 mg/m2 IV) in children treated with moderate to highly emetogenic chemotherapy. This study needs to be confirmed in a larger randomized trial.

**Gastroenteritis**

For nausea and vomiting associated with pediatric gastroenteritis, emphasis should be placed on oral rehydration therapy (ORT); several products are commercially available. However, a recent meta-analysis has shown that pharmacotherapy may be a useful adjunct to ORT. One double-blind study suggested that a single dose of ondansetron may facilitate ORT and reduced the need for IV fluids in children with gastroenteritis who were unable to tolerate oral intake. While promethazine given in suppository form was the most often prescribed antiemetic for pediatric gastroenteritis, the Food and Drug Administration added a black box warning due to serious adverse events reports in children and adolescents, including death.

**PHARMACOECONOMIC CONSIDERATIONS**

Cost of antiemetic drugs for the treatment of nausea and vomiting is only one variable to consider in a pharmacoeconomic outcome assessment. Other variables include the cost of managing complications and the impact on loss of work, functionality, and productivity as well as delays of potentially curable therapies. Inadequately controlled emesis can lead to unexpected hospitalizations for potentially serious complications including electrolyte deficiencies, dehydration, esophageal tears, and wound dehiscence.

It is economically and clinically important to develop antiemetic protocols based on appropriate decision analysis to optimize clinical outcomes. The clinical practice guidelines that have been previously described are valuable tools when developing institution-specific antiemetic protocols. The need to control antiemetic costs for health systems is universal and formulary management strategies have been described.

**CINV**

A large study based on claims data was used to determined the costs associated with CINV over one cycle of chemotherapy. Direct medical cost in the uncontrolled CINV group was estimated to be $1,300 (in 2006 U.S. dollars), or 30% higher than in the controlled CINV group. A sensitivity analysis demonstrated that a new antiemetic agent that could decrease the uncontrolled CINV rate from 50% to 10% would be cost-effective as long as the new drug cost is $500 or less.

**PONV**

As was presented earlier, the risk of developing PONV increases as the number of risk factors increase. Any occurrence of PONV would likely delay patient discharge from the post-anesthesia unit with a potential increase in the cost of patient care. Prophylactic antiemetic therapy was cost effective with a number needed to treat (NNT) of 3 to 4 (an NNT <5 is considered cost-effective). In low-risk patients, the NNT was about 20 and not cost-effective.

**EVALUATION OF EMETIC OUTCOMES**

In assessing emetic outcomes, standardized monitoring criteria should include the subjective assessment of the patient’s severity of nausea, as well as objective parameters, such as changes in patient weight, the number of vomiting episodes each day, the volume of vomitus lost, and evaluation of fluid, acid–base balance, and electrolyte status, with particular attention to serum sodium, potassium, and chloride concentrations. In addition, evaluation of renal function may become important, particularly in patients with volume contraction and progressive electrolyte disturbances. Specific parameters include daily urine volume, urine specific gravity, and urine electrolyte concentrations. Physical assessment of patients should include evaluation of mucous membranes and skin turgor, because dryness of these tissues may be indicative of significant volume loss.

For patients on chemotherapy, evaluation of emetic outcomes should occur after the administration of each chemotherapy cycle. Adherence to outpatient antiemetic regimens occurs in about 65% of patients. Delayed nausea and vomiting occurs in 15% to 40% of patients, depending on the emetic risk of the chemotherapy and the antiemetic regimen used for prophylaxis. Patients receiving high risk regimens are most likely to report symptoms of nausea and vomiting on day 3 after chemotherapy. Symptom management assessments should be performed on the third or fourth day after chemotherapy. Documentation of a nausea and/or vomiting event will assist the clinician in modifying the antiemetic regimen for the next cycle of chemotherapy.
In the postsurgical anesthesia setting, assessment of nausea and vomiting is important for detecting dehydration, decreased blood pressure, or cardiac arrhythmias. Other complications of PONV include suture line tension, wound dehiscence, and increased bleeding under surgical flaps.81

Diarrhea, Constipation, and Irritable Bowel Syndrome

PATRICIA H. POWELL AND VIRGINIA H. FLEMING

KEY CONCEPTS

1. Diarrhea is caused by many viral and bacterial organisms. It is most often a minor discomfort, not life threatening, and usually self-limited.

2. The four pathophysiologic mechanisms of diarrhea have been linked to the four broad diarrheal groups, which are secretory, osmotic, exudative, and altered intestinal transit. The three mechanisms by which absorption occurs from the intestines are active transport, diffusion, and solvent drag.

4. Bismuth subsalicylate is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler’s diarrhea, but may cause interactions with several components if given in excess.

5. Underlying causes of constipation should be identified when possible and corrective measures taken (e.g., alteration of diet or treatment of diseases such as hypothyroidism).

6. The foundation of treatment of constipation is dietary fiber or bulk-forming laxatives that provide 10–15 g/day of raw fiber.

7. Irritable bowel syndrome (IBS) is one of the most common gastrointestinal disorders characterized by lower abdominal pain, disturbed defecation, and bloating. Many nongastrointestinal manifestations also exist with IBS. Visceral hypersensitivity is a major culprit in the pathophysiology of the disease.

8. Dietary-predominant IBS should be managed by dietary modification and drugs such as loperamide when diet changes alone are insufficient to promote control of symptoms.

9. Several drug classes are useful in the treatment of the pain associated with IBS including tricyclic compounds and the gut-selective calcium channel blockers.

DIARRHEA

Diarrhea is a troublesome discomfort that affects most individuals in the United States at some point in their lives and can be thought of as both a symptom and a sign. Usually diarrheal episodes begin abruptly and subside within 1 or 2 days without treatment. This chapter focuses primarily on noninfectious diarrhea, with only minor reference to infectious diarrhea (see Chap. 122 for a discussion of gastrointestinal infections). Diarrhea is often a symptom of a systemic disease, and not all possible causes of diarrhea are discussed in this chapter. Acute diarrhea is commonly defined as <14 days’ duration, persistent diarrhea as more than 14 days’ duration, and chronic diarrhea as more than 30 days’ duration.

To understand diarrhea, one must have a reasonable definition of the condition; unfortunately, the literature is extremely variable on this. Simply put, diarrhea is an increased frequency and decreased consistency of fecal discharge as compared to an individual’s normal bowel pattern. Frequency and consistency are variable within and between individuals. For example, some individuals defecate as often as three times per day, whereas others defecate only two or three times per week. A Western diet usually produces a daily stool weighing between 100 and 300 g, depending on the amount of nonabsorbable materials (mainly carbohydrates) consumed. Patients with serious diarrhea may have a daily stool weight in excess of 300 g; however, a subset of patients experience frequent small, watery passages. Additionally, vegetable fiber-rich diets, such as those consumed in some Eastern cultures (e.g., those in Africa), produce stools weighing more than 300 g/day.

Diarrhea may be associated with a specific disease of the intestines or secondary to a disease outside the intestines. For instance, bacillary dysentery directly affects the gut, whereas diabetes mellitus causes neuropathic diarrheal episodes. Furthermore, diarrhea can be considered as acute or chronic disease. Infectious diarrhea is often acute; diabetic diarrhea is chronic. Congenital disorders in gastrointestinal ion-transport mechanisms are another cause of chronic diarrhea. Whether acute or chronic, diarrhea has the same pathophysiologic causes that help in identification of specific treatments.

EPIDEMIOLOGY

The epidemiology of diarrhea varies in developed versus developing countries. In the United States, diarrheal illnesses are usually not reported to the Centers for Disease Control and Prevention (CDC) unless associated with an outbreak or an unusual organism or condition. For example, the acquired immunodeficiency syndrome (AIDS) has been identified with protracted diarrheal illness. Diarrhea is a major problem in daycare centers and nursing homes, probably because early childhood and senescence plus environmental conditions are risk factors. Although an exact
epidemiologic profile in the United States is not available through the CDC or published literature, chronic diarrhea affects approximately 5% of the adult population and ranges from 3% to 20% in children worldwide. In developing countries, diarrhea is a leading cause of illness and death in children, creating a tremendous economic strain on healthcare costs.

1. Most cases of acute diarrhea are caused by infections with viruses, bacteria, or protozoa and are generally self-limited. Although viruses are more commonly associated with acute gastrointestinalitis, bacteria are responsible for more cases of acute diarrhea.

Evaluation of a noninfectious cause is considered if diarrhea persists and no infectious organism can be identified, or if the patient falls into a high-risk category for metabolic complications with persistent diarrhea. Common causative bacterial organisms include Shigella, Salmonella, Campylobacter, Staphylococcus, and Escherichia coli. Foodborne bacterial infection is a major concern, as several major food poisoning episodes have occurred that were traced to poor sanitary conditions in meat-processing plants. Acute viral infections are attributed mostly to the Norwalk and rotavirus groups.

PHYSIOLOGY

In the fasting state, 9 L of fluid enters the proximal small intestine each day. Of this fluid, 2 L are ingested through diet, while the remainder consists of internal secretions. Because of meat content, duodenal chyme is usually hypertonic. When chyme reaches the ileum, the osmolarity adjusts to that of plasma, with most dietary fat, carbohydrate, and protein being absorbed. The volume of ileal chyme decreases to about 1 L/day upon entering the colon, which is further reduced by colonic absorption to 100 mL daily. If the small intestine water absorption capacity is exceeded, chyme overloads the colon, resulting in diarrhea. In humans, the colon absorptive capacity is about 5 L daily. Colonic fluid transport is critical to water and electrolyte balance.

Absorption from the intestines back into the blood occurs by three mechanisms: active transport, diffusion, and solvent drag. Active transport and diffusion are the mechanisms of sodium transport. Because of the high luminal sodium concentration (142 mEq/L), sodium diffuses from the sodium-rich gut into epithelial cells, where it is actively pumped into the blood and exchanged with chloride to maintain an isolectric condition across the epithelial membrane.

Hydrogen ions are transported by an indirect mechanism in the upper small intestine. As sodium is absorbed, hydrogen ions are secreted into the gut. Hydrogen ions then combine with bicarbonate ions to form carbonic acid, which then dissociates into carbon dioxide and water. Carbon dioxide readily diffuses into the blood for expiration through the lung. The water remains in the chyme.

Paracellular pathways are major routes of ion movement. As ions, monosaccharides, and amino acids are actively transported, an osmotic pressure is created, drawing water and electrolytes across the intestinal wall. This pathway accounts for significant amounts of ion transport, especially sodium. Sodium plays an important role in stimulating glucose absorption. Glucose and amino acids are actively transported into the blood via a sodium-dependent cotransport mechanism. Cotransport absorption mechanisms of glucose-sodium and amino acid-sodium are extremely important for treating diarrhea.

Gut motility influences absorption and secretion. The amount of time in which luminal content is in contact with the epithelium is under neural and hormonal control. Neurohormonal substances, such as angiotensin, vasopressin, glucocorticoid, aldosterone, and neurotransmitters also regulate ion transport.

PATHOPHYSIOLOGY

Four general pathophysiologic mechanisms disrupt water and electrolyte balance, leading to diarrhea, and are the basis of diagnosis and therapy. These are (a) a change in active ion transport by either decreased sodium absorption or increased chloride secretion; (b) change in intestinal motility; (c) increase in luminal osmolality; and (d) increase in tissue hydrostatic pressure. These mechanisms have been related to four broad clinical diarrheal groups: secretory, osmotic, exudative, and altered intestinal transit.

Secretory diarrhea occurs when a stimulating substance either increases secretion or decreases absorption of large amounts of water and electrolytes. Substances that cause excess secretion include vasoactive intestinal peptide (VIP) from a pancreatic tumor, unabsorbed dietary fat in steatorrhea, laxatives, hormones (such as secretion), bacterial toxins, and excessive bile salts. Many of these agents stimulate intracellular cyclic adenosine monophosphate and inhibit Na+/K+-adenosine triphosphatase (ATPase), leading to increased secretion. Also, many of these mediators inhibit ion absorption simultaneously. Secretory diarrhea is recognized by large stool volumes (>1 L/day) with normal ionic contents and osmolality approximately equal to plasma. Fasting does not alter the stool volume in these patients.

Poorly absorbed substances retain intestinal fluids, resulting in osmotic diarrhea. This process occurs with malabsorption syndromes, lactose intolerance, administration of divalent ions (e.g., magnesium-containing antacids), or consumption of poorly soluble carbohydrate (e.g., lactulose). As a poorly soluble solute is transported, the gut adjusts the osmolality to that of plasma; in so doing, water and electrolytes flux into the lumen. Clinically, osmotic diarrhea is distinguishable from other types, as it ceases if the patient resorts to a fasting state.

Inflammatory diseases of the gastrointestinal tract discharge mucus, serum proteins, and blood into the gut. Sometimes bowel movements consist only of mucus, exudate, and blood. Exudative diarrhea affects other absorptive, secretory, or motility functions to account for the large stool volume associated with this disorder.

Altered intestinal motility produces diarrhea by three mechanisms: reduction of contact time in the small intestine, premature emptying of the colon, and bacterial overgrowth. Chyme must be exposed to intestinal epithelium for a sufficient time period to enable normal absorption and secretion processes to occur. If this contact time decreases, diarrhea results. Intestinal resection or bypass surgery and drugs (such as metoclopramide) cause this type of diarrhea. On the other hand, an increased time of exposure allows fecal bacteria overgrowth. A characteristic small intestine diarrheal pattern is rapid, small, coupling bursts of waves. These waves are inefficient, do not allow absorption, and rapidly dump chyme into the colon. Once in the colon, chyme exceeds the colonic capability to absorb water.

Etiologic Examination of the Stool

Stool characteristics are important in assessing the etiology of diarrhea. A description of the frequency, volume, consistency, and color provides diagnostic clues. For instance, diarrhea starting in the small intestine produces a copious, watery or fatty (greasy), and foul-smelling stool; contains undigested food particles; and is usually free from gross blood. Colonic diarrhea appears as small, pasty, and sometimes bloody or mucoid movements. Rectal tenesmus with flatus accompanies large intestinal diarrhea.

CLINICAL PRESENTATION

Table 43–1 outlines the clinical presentation of diarrhea and Table 43–2 shows common drug-induced causes of diarrhea.
Clinical Presentation of Diarrhea

**General**
- Usually, acute diarrheal episodes subside within 72 hours of onset, whereas chronic diarrhea involves frequent attacks over extended time periods.

**Signs and symptoms**
- Abrupt onset of nausea, vomiting, abdominal pain, headache, fever, chills, and malaise.
- Bowel movements are frequent and never bloody, and diarrhea lasts 12 to 60 hours.
- Intermittent periumbilical or lower right quadrant pain with cramps and audible bowel sounds is characteristic of small intestinal disease.
- When pain is present in large-intestinal diarrhea, it is a gripping, aching sensation with tenesmus (straining, ineffective, and painful stooling). Pain localizes to the hypogastric region, right or left lower quadrant, or sacral region.
- In chronic diarrhea, a history of previous bouts, weight loss, anorexia, and chronic weakness are important findings.

**Physical examination**
- Typically demonstrates hyperperistalsis with borborygmi and generalized or local tenderness.

**Laboratory tests**
- Stool analysis studies include examination for microorganisms, blood, mucus, fat, osmolality, pH, electrolyte and mineral concentration, and cultures.
- Stool test kits are useful for detecting gastrointestinal viruses, particularly rotavirus.
- Antibody serologic testing shows rising titers over a 3- to 6-day period, but this test is not practical and is nonspecific.
- Occasionally, total daily stool volume is also determined.
- Direct endoscopic visualization and biopsy of the colon may be undertaken to assess for the presence of conditions such as colitis or cancer.
- Radiographic studies are helpful in neoplastic and inflammatory conditions.

**TREATMENT**

**Diarrhea**

**PREVENTION**
Acute viral diarrheal illness often occurs in daycare centers and nursing homes. Because person-to-person contact is the mechanism by which viral disease spreads, isolation techniques must be initiated. For bacterial, parasitic, and protozoal infections, strict food handling, sanitation, water, and other environmental hygiene practices can prevent transmission. If diarrhea is secondary to another illness, controlling the primary condition is necessary. Antibiotics and bismuth subsalicylate are advocated to prevent traveler’s diarrhea, in conjunction with treatment of drinking water and caution with consumption of fresh vegetables.7

**DESIRED OUTCOME**
- If prevention is unsuccessful and diarrhea occurs, therapeutic goals are to (a) manage the diet; (b) prevent excessive water, electrolyte, and acid-base disturbances; (c) provide symptomatic relief; (d) treat curable causes; and (e) manage secondary disorders causing diarrhea (Figs. 43–1 and 43–2).

Clinicians must clearly understand that diarrhea, like a cough, may be a body defense mechanism for ridding itself of harmful substances or pathogens. The correct therapeutic response is not necessarily to stop diarrhea at all costs.

**NONPHARMACOLOGIC MANAGEMENT**
Dietary management is a first priority in the treatment of diarrhea. Most clinicians recommend discontinuing consumption of solid foods and dairy products for 24 hours. However, fasting is of questionable value, as this treatment modality has not been extensively studied. In osmotic diarrhea, these maneuvers control the problem. If the mechanism is secretory, diarrhea persists. For patients who are experiencing nausea and/or vomiting, a mild, digestible, low-residue diet should be administered for 24 hours. If vomiting is present and uncontrollable with antiemetics (see Chap. 42), nothing is taken by mouth. As bowel movements decrease, a bland diet is begun.

Feeding should continue in children with acute bacterial diarrhea. Fed children have less morbidity and mortality, whether or not they receive oral rehydration fluids. Studies are not available in the elderly or in other high-risk groups to determine the value of continued feeding in bacterial diarrhea.

**Water and Electrolytes**
Rehydration and maintenance of water and electrolytes are primary treatment goals until the diarrheal episode ends. If the patient is volume depleted, rehydration should be directed at replacing water...
and electrolytes to normal body composition. Then water and electrolyte composition are maintained by replacing losses. Many patients will not develop volume depletion and therefore will only require maintenance fluid and electrolyte therapy. Parenteral and enteral routes may be used for supplying water and electrolytes. If vomiting and dehydration are not severe, enteral feeding is the less costly and preferred method. In the United States, many commercial oral rehydration preparations are available (see Table 43–4), and diet. (RBC, red blood cells; WBC, white blood cells.)

**FIGURE 43-1.** Recommendations for treating acute diarrhea. Follow these steps: (a) Perform a complete history and physical examination. (b) Is the diarrhea acute or chronic? If chronic diarrhea, go to Figure 43–2. (c) If acute diarrhea, check for fever and/or systemic signs and symptoms (i.e., toxic patient). If systemic illness (fever, anorexia, or volume depletion), check for an infectious source. If positive for infectious diarrhea, use appropriate antibiotic/anthelmintic drug and symptomatic therapy. If negative for infectious cause, use only symptomatic treatment. (d) If no systemic findings, then use symptomatic therapy based on severity of volume depletion, oral or parenteral fluid/electrolytes, and anti-diarrheal agents (see Table 43–4), and diet. (RBC, red blood cells; WBC, white blood cells.)

**Opiates and Their Derivatives**

Opiates and opioid derivatives (a) delay the transit of intraluminal contents or (b) increase gut capacity, prolonging contact and absorption. Enkephalins, which are endogenous opioid substances, regulate fluid movement across the mucosa by stimulating absorptive processes. Limitations to the use of opiates include an addiction potential (a real concern with long-term use) and worsening of diarrhea in selected infectious diarrhea.

Most opiates act through peripheral and central mechanisms with the exception of loperamide, which acts only peripherally. Loperamide is antisecretory; it inhibits the calcium-binding protein calmodulin, controlling chloride secretion. Loperamide, available as 2 mg capsules or 1 mg/5 mL solution (both are nonprescription products), is suggested for managing acute and chronic diarrhea. The usual adult dose is initially 4 mg orally, followed by 2 mg after each loose stool, up to 16 mg/day. Used correctly, this agent has rare side effects, such as dizziness and constipation. If the diarrhea is concurrent with a high fever or bloody stool, the patient should be referred to a physician. Also, diarrhea lasting 48 hours beyond initiating loperamide warrants medical attention. Loperamide can also be used in traveler’s diarrhea. It is comparable to bismuth subsalicylate for treatment of this disorder.

 Diphenoxylate is available as a 2.5 mg tablet and as a 2.5 mg/5 mL solution. A small amount of atropine (0.025 mg) is included in the product to discourage abuse. In adults, when taken as 2.5 to 5 mg three or four times daily, not to exceed a 20 mg total daily dose, diphenoxylate is rarely toxic. Some patients may complain of atropinism (blurred vision, dry mouth, and urinary hesitancy). Like loperamide, it should not be used in patients who are at risk of bacterial enteritis with *E. coli*, *Shigella*, or *Salmonella*. 

**PHARMACOLOGIC THERAPY**

Various drugs have been used to treat diarrheal attacks (Table 43–4), including antimotility agents, adsorbents, antisecretory compounds, antibiotics, enzymes, and intestinal microflora. Usually these drugs are not curative but palliative.
Difenoxin, a diphenoxylate derivative also chemically related to meperidine, is also combined with atropine and has the same uses, precautions, and side effects. Marketed as a 1 mg tablet, the adult dosage is 2 mg initially, followed by 1 mg after each loose stool, not to exceed 8 mg/day.

Paregoric, camphorated tincture of opium, is marketed as a 2 mg/5 mL solution and is indicated for managing both acute and chronic diarrhea. It is not widely prescribed today because of its abuse potential.

**Adsorbents**

Adsorbents are used for symptomatic relief. These products, many not requiring a prescription, are nontoxic, but their effectiveness remains unproven. Adsorbents are nonspecific in their action; they adsorb nutrients, toxins, drugs, and digestive juices. Polycarbophil absorbs 60 times its weight in water and can be used to treat both diarrhea and constipation. It is a nonprescription product and is sold as a 500 mg chewable tablet. This hydrophilic, nonabsorbable product is safe and may be taken four times daily, up to 6 g/day in adults. See Table 43–4 for selected antidiarrheal preparations.

**Antisecretory Agents**

Bismuth subsalicylate appears to have antisecretory, antiinflammatory, and antibacterial effects. As a nonprescription product, it is marketed for indigestion, relieving abdominal cramps, and controlling diarrhea, including traveler’s diarrhea. Bismuth subsalicylate dosage strengths are a 262 mg chewable tablet, 262 mg/5 mL liquid, and 524 mg/15 mL liquid. The usual adult dose is 2 tablets or 30 mL every 30 minutes to 1 hour up to 8 doses per day.

Bismuth subsalicylate contains multiple components that might be toxic if given excessively to prevent or treat diarrhea. For instance, an active ingredient is salicylate, which may interact with anticoagulants or may produce salicylism (tinnitus, nausea, and vomiting). Bismuth reduces tetracycline absorption and may interfere with select gastrointestinal radiographic studies. Patients may complain of a darkening of the tongue and stools with repeat

administration. Salicylate can induce gout attacks in susceptible individuals.

Bismuth subsalicylate suspension has been evaluated in the treatment of secretory diarrhea of infectious etiology as well. In a dose of 30 mL every 30 minutes for eight doses, unformed stools decrease in the first 24 hours. Bismuth subsalicylate may also be effective in preventing traveler’s diarrhea.

Octreotide, a synthetic octapeptide analog of endogenous somatostatin, is effective for the symptomatic treatment of carcinoid tumors and other peptide-secreting tumors, dumping syndrome, and chemotherapy-induced diarrhea. It has had limited success in patients with AIDS-associated diarrhea and short-bowel syndrome, does not appear to have an advantage over various opiate derivatives in the treatment of chronic idiopathic diarrhea, and has the disadvantage of being administered by injection.

|                                    | 300 mg/tablet                      |                                                |

| Antisecretory                       |                                    |                                                |
| Bismuth subsalicylate               | 1050 mg/50 mL                      | Two tablets or 30 mL every 30 min to 1 h as needed up to 8 doses/day |
|                                    | 262 mg/15 mL                       |                                                |
|                                    | 524 mg/15 mL                       |                                                |
|                                    | 262 mg/tablet                      |                                                |
| Enzymes (lactase)                   | 1,250 neutral lactase units/4 drops| 3–4 drops taken with milk or dairy product     |
|                                    | 3,500 FCC lactase units per tablet |                                                |
| Bacterial replacement (*Lactobacillus acidophilus, Lactobacillus bulgaricus*) |                                    |                                                |
|                                    | 2 tablets or 1 granule packet three to four times daily; give with milk, juice, or water | |

| Octreotide                          |                                    |                                                |
|                                    | 0.05 mg/mL                         | Initial: 50 mcg subcutaneously                 |
|                                    | 0.1 mg/mL                          | One to two times per day and titrate dose based on indication up to 600 mcg/day in two to four divided doses |
|                                    | 0.5 mg/mL                          |                                                |

The dose of octreotide varies with the indication, disease severity, and patient response. For managing diarrhea and flushing associated with carcinoid tumors in adults, the initial dosage range is 100 to 600 mcg/day in two to four divided doses subcutaneously for 2 weeks. For controlling secretory diarrhea of VIPomas, the dosage range is 200 to 300 mcg/day in two to four divided doses for 2 weeks. Some patients may require higher doses for symptomatic control. Patients responding to these initial doses may be switched to Sandostatin LAR Depot, a long-acting octreotide formulation. This product consists of microspheres containing the drug. Initial doses consist of 20 mg given intramuscularly intragluteally at 4-week intervals for 2 months. It is recommended that during the first 2 weeks of therapy the short-acting formulation also be administered subcutaneously. At the end of 2 months, patients with good symptom control may have the dose reduced to 10 mg every 4 weeks, while those without sufficient symptom control may have the dose increased to 30 mg every 4 weeks. For patients experiencing recurrence of symptoms on the 10 mg dose, dosage adjustment to 20 mg should be made. It is not uncommon for patients with carcinoid tumors or VIPomas to experience periodic exacerbation of symptoms. Subcutaneous octreotide for several days should be re instituted in these individuals. In so-called carcinoid crisis, octreotide is given as an intravenous infusion at 50 mcg/h for 8 to 24 hours.

Because octreotide inhibits many other gastrointestinal hormones, it has a variety of intestinal side effects. With prolonged use,
gallbladder and biliary tract complications such as cholelithiasis have been reported. Approximately 5% to 10% of patients complain of nausea, diarrhea, and abdominal pain. Local infection pain occurs with about an 8% incidence. With high doses, octreotide may reduce dietary fat absorption, leading to steatorrhea.

Two other somatostatin analogs, lanreotide and vapreotide, have been studied.14,15 Lanreotide is approved for use in the United States for acromegaly. The starting dose is 90 mg subcutaneously every 4 weeks for 3 months, then the dose is adjusted based upon growth hormone and insulin-like growth factor levels.16 Vapreotide is an orphan drug that is indicated for pancreatic and gastrointestinal fistulas as well as esophageal variceal bleeding.

Miscellaneous Products

Probiotics are microorganisms that have been used for many years to replace colonic microflora. This supposedly restores normal intestinal function and suppresses the growth of pathogenic microorganisms. Saccharomyces boulardii, Lactobacillus GG, and Lactobacillus acidophilus have been shown to decrease the duration of infectious and antibiotic-induced diarrhea in adults and children.20 A combination probiotic product, VSL#3 (which contains multiple strains of lactobacilli and bifidobacteria) may have benefit in preventing radiation-induced diarrhea when given three times a day.21 The dosage of probiotic preparations varies depending on the brand used. Intestinal flatus is the primary patient complaint experienced with this modality.

Anticholinergic drugs such as atropine block vagal tone and prolong gut transit time. Drugs with anticholinergic properties are present in many nonprescription products. Their value in controlling diarrhea is questionable and limited because of side effects. Angle-closure glaucoma, selected heart diseases, and obstructive uropathies are relative contraindications to the use of anticholinergic agents.

Lactase enzyme products are helpful for patients who are experiencing diarrhea secondary to lactose intolerance. Lactase is required for carbohydrate digestion. When a patient lacks this enzyme, eating dairy products causes an osmotic diarrhea. Several products are available for use each time a dairy product, especially milk or ice cream, is consumed.

Investigational Drugs

Several new classes of compounds are undergoing clinical trials for efficacy in acute diarrhea.22 Enkephalins are endogenous opioid compounds in the gut that have antisecretory and proabsorptive activity in the small intestine. They promote sodium and chloride reabsorption via stimulation of a nonadrenergic, noncholinergic neurotransmitter. Enkephalinase inhibitors are compounds that slow down the enzymatic (i.e., enkephalinase) breakdown of endogenous enkephalins found in the small intestines. They exert an antisecretory effect without affecting GI motility or CNS-related effects/side effects. One specific compound, originally called acetorphan but now referred to as racemadol, has been extensively tested in humans and found to be equal to other opiate anti diarrheals such as loperamide, while causing less GI motility side effects such as abdominal bloating, pain, and constipation.20–22 Racemadol is currently licensed only in France and a few developing countries with a high incidence of childhood diarrhea.

Vaccines are a new therapeutic frontier in controlling infectious diarrheas, especially in developing countries. 25 – 24 An oral vaccine for cholera is licensed and available in other countries (Dukoral from Merck) and has fewer adverse effects than the previously available parenteral vaccine. However, the CDC does not recommend cholera vaccines for most travelers, nor is the vaccine available in the United States. Oral Shigella vaccine, although effective under field conditions, requires 5 weekly oral doses and repeat booster doses, thereby limiting its practicality for use in developing nations. With about 1,500 serotypes for Salmonella, a vaccine is not currently available for humans. There are two newer typhoid vaccine formulations, one a parenteral inactivated whole-cell vaccine and the other an oral live-attenuated (Ty21a) vaccine that is administered in four doses on days 1, 3, 5, and 7, to be completed at least 1 week before exposure. Two rotavirus vaccines have been shown to prevent gastroenteritis due to rotavirus infection in infants and children.23 The pentavalent human-bovine reassortant vaccine (RotarTaq from Merck) is administered as a three-oral-dose sequence, and the monovalent human vaccine (Rotarix from GlaxoSmithKline) is administered as a two-oral-dose sequence. A rotavirus vaccine program has been formed to reduce child morbidity and mortality from diarrheal disease by accelerating the availability of rotavirus vaccines appropriate for use in developing countries.

EVALUATION OF THERAPEUTIC OUTCOMES

General Outcomes Measures

Therapeutic outcomes are directed toward key symptoms, signs, and laboratory studies. Constitutional symptoms usually improve within 24 to 72 hours. Monitoring for changes in the frequency and character of bowel movements on a daily basis in conjunction with vital signs and improvement in appetite are of utmost importance. Also, the clinician needs to monitor body weight, serum osmolality, serum electrolytes, complete blood cell counts, urinalysis, and culture results (if appropriate).

Acute Diarrhea

Most patients with acute diarrhea experience mild to moderate distress. In the absence of moderate to severe dehydration, high fever, and blood or mucus in the stool, this illness is usually self-limiting within 3 to 7 days. Mild to moderate acute diarrhea is usually managed on an outpatient basis with oral rehydration, symptomatic treatment, and diet. Elderly persons with chronic illness as well as infants may require hospitalization for parenteral rehydration and close monitoring.

Severe Diarrhea

In the urgent/emergent situation, restoration of the patient’s volume status is the most important outcome. Toxic patients (fever dehydration, hematochezia, or hypotension) require hospitalization, intravenous fluids and electrolyte administration, and empiric antibiotic therapy while awaiting culture and sensitivity results. With timely management, these patients usually recover within a few days.

CONSTIPATION

Constipation is a commonly encountered medical condition in the United States for which many patients initiate self-treatment. Constipation also accounts for many emergency room, primary care, gastroenterologist, and pediatrician visits each year in the United States.26 Though often considered more of a minor uncomfortable or unpleasant problem, constipation can have serious consequences and be costly to the healthcare system. One of the major underlying problems contributing to constipation in the Western world is lack of adequate dietary fiber. An additional contributing factor is public misconception about normal
bowel function. Many people believe that daily bowel movements are required for normal health or that accumulation of toxic substances will occur with infrequent defecation. Inappropriate laxative use by the general public may result from these misconceptions.

Constipation does not have a single, generally agreed upon definition. A general definition from the American Gastroenterology Association (AGA) defines functional constipation as a bowel disorder characterized by difficult, infrequent, or seemingly incomplete defecation that does not meet criteria for irritable bowel syndrome (IBS). The lay public and healthcare professionals often define constipation in a number of both quantitative and qualitative ways. Physicians often use stool frequency to define constipation (most commonly fewer than three bowel movements per week); however, the "normal" frequency of bowel movement is not well established (and can vary from person to person). Patients more often describe constipation in terms of symptoms or a combination of quantitative and qualitative descriptors that are difficult to quantify: bowel movement frequency, stool size or consistency (hard or lumpy stools), straining upon defecation, inability to defecate at will, and symptoms such as sensation of incomplete evacuation.

Examples of definitions of constipation that have been used in clinical studies include the following: (a) fewer than three stools per week for women and five stools per week for men despite a high-residue diet, or a period of more than 3 days without a bowel movement; (b) straining (incomplete evacuation, hard/lumpy stools, etc.) at stool greater than 25% of the time and/or two or fewer stools per week; or (c) straining at defecation and less than one stool daily with minimal effort. A symptom-based system for classifying functional constipation (and other functional gastrointestinal disorders) called the Rome criteria is often used to define constipation in clinical trials today. The Rome criteria encompass both quantitative (frequency) and qualitative (stool consistency, etc.) symptoms associated with constipation. The most current revision of the criteria, Rome III, was released in 2006 and is outlined in Table 43–5.

**EPIDEMIOLOGY**

A systematic review of the epidemiology of constipation in North America reported a prevalence range for constipation of 1.9% to 27%, with most reported estimates ranging from 12% to 19%. Prevalence estimates by gender were female-to-male ratio of 2.2:1. Similarly, in a multinational survey of 13,879 adult participants from seven countries, the rate of self-reported constipation was 12.3% overall (range 5% to 18%). Constipation was more common in women (2.4-fold more likely) and the elderly. Other factors associated with constipation in some reports include inactivity, lower socioeconomic class, lower income, non-Caucasian race, symptoms of depression, and history of physical or sexual abuse.

Although bowel movement frequency does not decrease as a consequence of aging, there is an age-related increase in laxative use and self-reported constipation rates. Factors associated with the increased prevalence of constipation in the elderly include a higher number of daily medications, increased incidence of chronic comorbidities, changes in mobility status, changes in diet/lifestyle, and institutionalization.

**PATHOPHYSIOLOGY**

Constipation may be primary or secondary. Primary constipation occurs without an identifiable underlying cause, whereas secondary constipation may be the result of constipating drugs, lifestyle factors, or medical disorders (Table 43–6). Three primary constipation subtypes exist—normal transit, slow transit, and disordered defecation (also referred to by various other names such as pelvic floor dysfunction, anorectal dysynergia, outlet constipation, dys-coordinated pelvic muscle activity). Normal transit constipation is the most common and often referred to as “functional constipation.” These patients have normal GI motility and stool frequency but may experience difficulty evacuating, passage of hard stools, or bloating and abdominal discomfort. Slow transit constipation represents an abnormality of GI transit time that leads to infrequent defecation. Dysfunction of the pelvic floor muscles and/or

---

Although bowel movement frequency does not decrease as a consequence of aging, there is an age-related increase in laxative use and self-reported constipation rates. Factors associated with the increased prevalence of constipation in the elderly include a higher number of daily medications, increased incidence of chronic comorbidities, changes in mobility status, changes in diet/lifestyle, and institutinalization.
anal sphincter are the most frequently encountered reasons for disordered defecation. In patients with defecatory disorders, these muscles/sphincter (which normally relax during defecation) contract and impede evacuation of stool. It is common for the subtypes to overlap in a single patient.

Approaches to the treatment of constipation should begin with attempts to determine its cause. Disorders of the GI tract (IBS or diverticulitis), metabolic disorders (diabetes), or endocrine disorders (hypothyroidism) or other secondary causes may be involved. Constipation commonly results from a diet low in fiber and or from use of constipating drugs such as opiates. Finally, constipation may sometimes be psychogenic in origin. Each of these causes is discussed in the following sections.

**Constipation is a frequently reported problem in the elderly, probably the result of improper diets (low in fiber and liquids), decreasing number of daily medications, diminished abdominal wall muscular strength, and possibly diminished physical activity. However, as previously stated, the frequency of bowel movements is not decreased with normal aging.**

### Drug-Induced Constipation

Use of drugs that inhibit the neurologic or muscular function of the GI tract, particularly the colon, may result in constipation. The majority of cases of drug-induced constipation are caused by opiates, various agents with anticholinergic properties, and antacids containing aluminum or calcium. With most of the agents listed in Table 43–7, the inhibitory effects on bowel function are dose dependent, with larger doses clearly causing constipation more frequently.

Opiates have effects on all segments of the bowel, but effects are most pronounced on the colon. The major mechanism by which opiates produce constipation has been proposed to be prolongation of intestinal transit time by causing spastic, nonpropulsive contractions. An additional contributory mechanism may be an increase in electrolyte absorption.

All opiate derivatives are associated with constipation, but the degree of intestinal inhibitory effects seems to differ between agents. Orally administered opiates appear to have greater inhibitory effects than parenterally administered products. Orally administered enkephalins (endogenous opiate-like polypeptides) have antimotility properties. In some reports, transdermal fentanyl has been associated with less constipation than oral sustained-release morphine.}

#### Clinical Evaluation of Constipation

**History and physical examination**

- Clarify what the patient means by constipation, identifying specific signs and symptoms (i.e., infrequent bowel movements, stools that are hard, small, or dry; difficulty or pain of defecation, feeling of abdominal discomfort or bloating, incomplete evacuation, etc.)
- Ask specifically about presence of Alarm signs and symptoms
- Evaluate general health, psychological status, medications, diet, comorbidities, onset of symptoms, and what treatments have been tried
- Identify underlying secondary causes or conditions (Table 43–6)
- Perform rectal exam for presence of anatomical abnormalities (such as fistulas, fissures, hemorrhoids, rectal prolapse) or abnormalities of perianal descent. Digital examination of rectum to check for fecal impaction, anal stricture, or rectal mass.

**Laboratory tests**

- No routine recommendations for lab testing—as indicated by clinical discretion
- In patients with signs and symptoms suggestive of organic disorder, specific testing may be performed (i.e., thyroid-function tests, electrolytes, glucose, complete blood count) based on clinical presentation
- In patients with alarm signs and symptoms or when structural disease is a possibility, select appropriate diagnostic studies:
  1. Proctoscopy
  2. Sigmoidoscopy
  3. Colonoscopy
  4. Barium enema

#### CLINICAL PRESENTATION

See Table 43–8.

### TREATMENT

#### Constipation

**GENERAL APPROACH TO TREATMENT**

Evaluation of constipation should attempt to clarify the patient’s specific symptoms (i.e., exactly what the patient means by constipation). The patient should be asked about the frequency of bowel movements and the chronicity of constipation. Constipation occurring recently in an adult may indicate significant colon pathology such as malignancy. Constipation present since early infancy may be indicative of neurologic disorders. The patient should also be carefully questioned about usual diet and laxative regimens. Does the patient have a diet consistently deficient in high-fiber items and containing mainly highly refined foods? What laxatives or cathartics has the patient used to attempt relief of constipation? The patient should be questioned about other concurrent medications, with interest focused on agents that might cause constipation. Each patient should be questioned specifically to identify any “alarm symptoms” that would warrant further diagnostic workup (Table 43–9). Evaluation should also include assessment of general health status, signs of underlying medical illness (i.e., hypothyroidism), and psychological status (e.g., depression or other psychological illness).

For most patients who complain of constipation, a thorough physical examination is not required after it is established that constipation (a) is not a chronic problem, (b) is not accompanied by signs of significant GI disease (i.e., alarm symptoms such as rectal bleeding or anemia), and (c) does not cause severe discomfort. In these circumstances, the patient may be referred directly to the first-line therapies for constipation described in the next section (mainly

### Table 43–7: Drugs Causing Constipation

bulk-forming laxatives and dietary fiber with occasional use of saline or stimulant laxatives. Patients with alarm symptoms, with a family history of colon cancer, or those >50 years old with new symptoms may need further diagnostic evaluation. Table 43–10 presents a general treatment algorithm for the management of constipation.

The proper management of constipation requires a number of different modalities; however, the basis for therapy should be dietary modification in most cases. The major dietary change should be an increase in the amount of fiber consumed daily. In addition to dietary management, patients should be encouraged to alter other aspects of their lifestyle if necessary. Important considerations are to encourage patients to exercise (achieved even by brisk walking after dinner) and to adjust bowel habits so that a regular and adequate time is made to respond to the urge to defecate. Another general measure is to increase fluid intake. This is generally recommended and believed beneficial, although there is little objective evidence to support this measure.

If an underlying disease is recognized as the cause of constipation, attempts should be made to correct it. GI malignancies may be removed via surgical resection. Endocrine and metabolic derangements should be corrected by the appropriate methods. For example, when hypothyroidism is the cause of constipation, cautious institution of thyroid-replacement therapy is the most important treatment measure.

As discussed earlier, many drug substances may cause constipation. If a patient is consuming medications well known to cause constipation, consideration should be given to alternative agents. For some medications (e.g., antacids), nonconstipating alternatives exist. If no reasonable alternatives exist to the medication thought to be responsible for constipation, consideration should be given to lowering the dose. If a patient must remain on constipating medications, then more attention must be given to general measures for prevention of constipation, as discussed in the next section.

### NONPHARMACOLOGIC THERAPY

#### Dietary Modification and Bulk-Forming Agents

The most important aspect of therapy for constipation for the majority of patients is dietary modification to increase the amount of fiber consumed. Fiber, the portion of vegetable matter not digested in the human GI tract, increases stool bulk, retention of stool water, and rate of transit of stool through the intestine. The result of fiber therapy is an increased frequency of defecation. Also, fiber decreases intraluminal pressures in the colon and rectum, which is thought to be beneficial for diverticular disease and for IBS. The specific physiologic effects of fiber are not well understood.

Patients should be advised to gradually increase daily fiber intake to 20 to 25 grams, either through dietary changes or fiber supplement products. Fruits, vegetables, and cereals typically have the highest fiber content. Bran, a by-product of milling of wheat, is often added to foods to increase fiber content and contains a high amount of soluble fiber, which may be extremely constipating in larger doses. Raw bran is generally 40% fiber. Medicinal products, often called “bulk-forming agents,” such as psyllium hydrophilic colloids, methylcellulose, or polycarbophil, have properties similar to those of dietary fiber and may be taken as tablets, powders, or granules.

A trial of dietary modification with high-fiber content should be continued for at least 1 month before effects on bowel function are determined. Most patients begin to notice effects on bowel function 3 to 5 days after beginning a high-fiber diet, but some patients may require a considerably longer period of time. Patients should be cautioned that abdominal distension and flatus may be particularly troublesome in the first few weeks of fiber therapy, particularly with high bran consumption. Gradually increasing dietary fiber over a few weeks to the goal of 20 to 25 grams may help reduce some of the adverse abdominal effects. In most cases these problems resolve with continued use.

Bulk-forming laxatives have few adverse effects. The only major caution in the use of bulk-forming laxatives is that obstruction of the esophagus, stomach, small intestine, and colon has been reported when the agents have been consumed without sufficient fluid and in patients with intestinal stenosis.

### Surgery

In a small percentage of patients who present with complaints of constipation, surgical procedures are necessary because of the presence of colonic malignancies or GI obstruction from a number of other causes. In each case, the involved segment of intestine may be resected or revised. Surgery may be required in some endocrine
disorders that cause constipation, such as pheochromocytoma, which requires removal of a tumor.

Biofeedback

Patients with constipation due to pelvic floor dysfunction/disordered defecation may have a less favorable response to fiber therapy than other constipation subtypes. Many adult patients with functional defecatory disorders appear to benefit from pelvic floor retraining with biofeedback therapy. Success rates of 65–80% have been reported in controlled and uncontrolled studies. The value of biofeedback in children with chronic constipation has not been well demonstrated.

PHARMACOLOGIC THERAPY

Drug Regimens of Choice

For most patients, treatment and prevention of constipation should consist of bulk-forming agents in addition to dietary modifications that increase dietary fiber. A variety of products are available that provide adequate bulk. Whichever agent is chosen, it should be used daily and continued indefinitely in most patients, particularly those with chronic constipation.

For most persons with acute constipation, infrequent use (less than every few weeks) of laxative products is acceptable. Acute constipation may be relieved by the use of a tap-water enema or a glucer- in suppository; if neither is effective, the use of oral sorbitol, low-dose of bisacodyl or senna, low-dose polyethylene glycol (PEG) (Miralax), or saline laxatives (e.g., milk of magnesia) may provide relief. If laxative treatment is required for longer than 1 week, the person should be advised to consult a physician to determine if there is an underlying cause of constipation that requires treatment with other modalities.

For bedridden or geriatric patients, or others with chronic constipation, bulk-forming laxatives remain the first line of treatment, but the use of more potent laxatives may be required relatively frequently. When other than bulk-forming laxatives are used, they should be administered in the lowest effective dose and as infrequently as possible to maintain regular bowel function (more than three stools per week). Agents that may be used in these situations include “osmotic” laxatives such as sorbitol, lactulose, low-dose PEG, or perhaps milk of magnesia (magnesium hydroxide). “Stimulant” laxatives such as senna and bisacodyl may also be used but because these agents can have a less desirable side effect profile, they may be reserved for patients who fail to respond to osmotic laxatives and increased daily fiber. Mineral oil should be avoided, particularly in bedridden patients, because of the risk of aspiration and lipid pneumonia. Some patients with chronic constipation may present with fecal impactions. Before vigorous oral laxatives can be used, the impaction needs to be removed using mechanical methods, including tap-water or saline enemas and digital extraction.

In the hospitalized patient without GI disease, constipation may be related to the use of general anesthesia and/or opiate substances. Most orally or rectally administered laxatives may be used in these situations. For prompt initiation of bowel evacuation, either a tap-water enema, glycerin suppository, or oral milk of magnesia is recommended. Several new agents that are peripheral opioid-receptor antagonists may be used in specific patient populations (postsurgical, hospitalized, and/or palliative care patients receiving chronic opioid therapy).

With infants and children, constipation may occur commonly. In patients with persistent problems, the underlying etiology may be neurologic, metabolic, or secondary to anatomic abnormalities. Management of constipation in this age group should consist of dietary modification with an emphasis on high-fiber foods or treatment of underlying cause. For acute constipation in most age groups, a tap-water enema or glycerin suppository may be helpful. Occasional use of osmotic or stimulant laxatives in low doses is justified as well.

Drug Classes

The traditional classification system for laxatives and cathartics by suspected mode of action may not be very useful, as the mode of action is not clearly understood for many agents. In general, most of these products induce bowel evacuation by one or more of the mechanisms associated with the etiology of diarrhea, including active electrolyte secretion, decreased water and electrolyte absorption, increased intraluminal osmolarity, and increased hydrostatic pressure in the gut. Laxatives convert the intestine from primarily an organ that absorbs water and electrolytes to an organ that secretes these substances. Identification of laxative agents by traditional classification system however, is important as this nomenclature is often used by other healthcare practitioners and in the medical literature (Table 43-11). The three general classes of laxatives are discussed in this section: (a) those causing softening of feces in 1 to 3 days (bulk-forming lax-atives, docusates, the poorly absorbable sugars (lactulose and sorbitol), and low-dose PEG); (b) those that result in soft or semifluid stool in 6 to 12 hours (diphenylmethane derivatives and anthraqui-none derivatives; “stimulant-type” laxatives); and (c) those causing water evacuation in 1 to 6 hours (saline cathartics, castor oil, and high-dose polyethylene glycol-electrolyte lavage solution).

Emollient Laxatives

Emollient laxatives are surfactant agents, docusate in its various salts, which work by facilitating mixing of aqueous and fatty material within the intestinal tract. They may increase water and electrolyte secretion in the small and large bowel. Increased stool moisture content should lead to a softer, easier-to-pass stool. These products are generally given orally, although docusate potassium has also

been used rectally. With these products, softening of stools occurs within 1 to 3 days of therapy.

Emollient laxatives are ineffective in treating constipation but are used mainly to prevent this condition. They may be helpful in situations in which straining at stool should be avoided, such as after recovery from myocardial infarction, with acute perianal disease, or after rectal surgery. It is unlikely that these agents would be effective in preventing constipation if major causative factors (e.g., heavy opiate use, uncorrected pathology, or inadequate dietary fiber) are not concurrently addressed.

Although docusates are generally safe, a few adverse effects have been noted. They may increase the intestinal absorption of agents administered concurrently and alter toxic potential. Reports of increased fecal soiling associated with docusate use in elderly patients may limit their use in this population.38

**Mineral Oil**

Mineral oil is the only lubricant laxative in routine use. This agent, obtained from petroleum refining, acts by coating stool and allowing for easier passage. It inhibits colonic absorption of water, thereby increasing stool weight and decreasing stool transit time. Mineral oil may be given orally or rectally in a dose of 15 to 45 mL. Generally, the effect on bowel function is noted after 2 or 3 days of use.

Mineral oil is helpful in situations similar to those suggested for docusates: to maintain a soft stool and to avoid straining for relatively short periods of time (a few days to 2 weeks); however, it possesses a much greater potential for adverse effects, and its routine use should be discouraged. Mineral oil may be absorbed systemically and can cause a foreign-body reaction in lymphoid tissue. Also, in debilitated or recumbent patients, mineral oil may be aspirated, causing lipoid pneumonia.30,38 Mineral oil may decrease the absorption of fat-soluble vitamins (A, D, E, and K) with chronic use by causing retention in the GI tract. Finally, even when given orally, mineral oil may leak from the anal sphincter, causing pruritus and soiling of clothing.

**Lactulose and Sorbitol**

Lactulose is a nonabsorbable disaccharide that is used orally or rectally. It is metabolized by colonic bacteria to low-molecular-weight acids, resulting in an osmotic effect whereby fluid is retained in the colon. The fluid retained in the colon lowers the pH and increases colonic peristalsis. Lactulose increases stool frequency and consistency in patients with chronic constipation (vs. placebo) and may be more effective than fiber alone. Head-to-head studies suggest that lactulose is slightly less effective than low-dose PEG or some combination laxative agents (such as those containing fiber plus senna—not currently available in the United States). Lactulose is generally not recommended as a first-line agent for the treatment of constipation because it is costly, requires a prescription, and is associated with adverse effects such as flatulence, nausea, and abdominal discomfort or bloating—though it can be useful in some patients. It may be justified as an alternative for acute constipation or in patients with an inadequate response to increased dietary fiber and bulking agents. In some patients with more complex disease or nonmodifiable risk factors for constipation (such as beribdered, elderly patients with chronic or debilitating illnesses and constipating medications), lactulose may be required on a more regular basis. In addition to the adverse abdominal effects associated with lactulose, diarrhea and electrolyte imbalances can occasionally occur.30 Sorbitol, a monosaccharide, also exerts its effect by osmotic action and has been recommended as a cost-effective alternative to lactulose. It is as effective as lactulose but may cause less nausea and is much less expensive.37,38

**Diphenylmethane and Anthraquinone Derivatives**

Bisacodyl, the only remaining diphenylmethane derivative with the withdrawal of phenolphthalein, exerts its therapeutic effect by stimulating the mucosal nerve plexus of the colon and may also affect intestinal fluid secretion by altering fluid and electrolyte transport. Bisacodyl exhibits significant interpatient variability in effective dose, with doses that cause no effect in one patient or resulting in excessive cramping and fluid evacuation in others. Bisacodyl is generally reserved for intermittent use (every few weeks) to treat constipation or as a bowel preparation before diagnostic procedures in which cleansing of the colon is necessary. It may be administered orally or as a suppository, both recommended once daily. Bisacodyl may sometimes cause severe abdominal cramping as well as significant fluid and electrolyte imbalances with chronic use.

Senna or sennosoids are the only remaining anthraquinone derivatives after removal of cascara sagrada and casanthrone (cascara extracts). Laxative effects are limited to the colon, and stimulation of the Auerbach plexus may be involved. As with bisacodyl, senna is only generally recommended for intermittent use. Senna-containing products are given orally.

In the past, clinicians have hesitated to use stimulant-type laxatives on a regular basis due to claims that the colon was harmed by chronic use. Stimulant laxatives were thought to cause cathartic colon, damage the enteric nervous system, and lead to a physical dependence on laxatives for defecation. There is little evidence that stimulant laxatives given in appropriate doses (not more than once daily) cause intestinal/enteric damage or physical dependency (the role of psychological dependency is a separate issue discussed in the laxative abuse section).30 Excessive use or abuse of stimulant laxatives, however, is a concern with these agents and can result in large-volume watery diarrhea, fluid loss, and electrolyte disturbances. Melanosis coli, a change in colon pigmentation with chronic anthraquinone therapy once thought to be linked to colon cancer, is now known to be a benign and reversible condition. Though safety may be of less concern than previously thought, because of their risk of adverse effects (abdominal cramping and fluid/electrolyte imbalance), stimulants are typically reserved for intermittent use or in patients who fail to respond adequately to bulking and osmotic laxatives. However, some patients with severe chronic constipation and nonmodifiable risk factors may use these agents on a more regular basis.

**Saline Cathartics**

Saline cathartics are composed of relatively poorly absorbed ions such as magnesium, sulfate, phosphate, and citrate, which produce their effects primarily by osmotic action causing retention of fluid in the GI tract. Magnesium also stimulates the secretion of cholecystokinin, a hormone that causes stimulation of bowel motility and fluid secretion. These agents may be given orally or rectally. A bowel movement may result within a few hours after oral doses and in 1 hour or less after rectal administration.

These agents should be used primarily for acute evacuation of the bowel, which may be necessary before diagnostic examinations, after poisonings, and in conjunction with some anthelmintics to eliminate parasites. Such agents as milk of magnesia (an 8% suspension of magnesium hydroxide) may be used occasionally (every few weeks) to treat constipation in otherwise healthy adults. Saline cathartics should not be used on a routine basis. The enema formulations of these agents may be useful in fecal impactions.

As with most laxatives, these agents may cause fluid and electrolyte depletion. Also, magnesium or sodium accumulation may occur when magnesium-containing cathartics are used in patients.
with renal dysfunction or when sodium phosphate is used in patients with congestive heart failure. These risks increase with long-term use.

**Castor Oil**

Castor oil is metabolized in the GI tract to an active compound, ricinoleic acid, which stimulates secretory processes, decreases glucose absorption, and promotes intestinal motility, primarily in the small intestine. Castor oil usually results in a bowel movement within 1 to 3 hours of administration. Because the agent has such a strong purgative action, it should not be used for the routine treatment of constipation.

**Glycerin**

Glycerin is usually administered as a 3 g suppository and exerts its effect by osmotic action in the rectum. As with most agents given as suppositories, the onset of action is usually less than 30 minutes. Glycerin is considered a safe laxative, although it may occasionally cause rectal irritation. Its use is acceptable on an intermittent basis for constipation, particularly in children.

**Polyethylene Glycol-Electrolyte Lavage Solution**

Whole-bowel irrigation with polyethylene glycol-electrolyte lavage solution (PEG-ELS) has become popular for colon cleansing before diagnostic procedures or colorectal operations. Various preparations are available (of varying molecular weights) with and without electrolytes.

Four liters of this solution is administered over 3 hours to obtain complete evacuation of the GI tract. The lavage solution is not recommended for routine treatment of constipation, and its use should be avoided in patients with intestinal obstruction.

Low doses of PEG, however, are FDA-approved for treatment of constipation. For this indication, PEG is administered in smaller volumes (10–30 g or 17–34 g per 120–240 mL) usually once (or twice) daily. With lesser volumes and slower ingestion, PEG has a much lower incidence of the adverse abdominal effects or electrolyte disturbances associated with whole-bowel lavage. PEG may also have fewer side effects than other “osmotic” agents because it is not absorbed systemically or metabolized by colonic bacteria. PEG has been safely tolerated even when used for longer durations of therapy (up to 6 months). PEG was first approved as a prescription laxative for occasional constipation in 1999. In 2006, PEG 3350 gained FDA approval for nonprescription treatment of occasional constipation under the brand name Miralax.

**Lubiprostone**

Lubiprostone is the first new drug in a class called “chloride channel activators,” which are designed to act locally in the gut to open chloride channels on the GI luminal epithelium, which, in turn, stimulates chloride-rich fluid secretion into the intestinal lumen. Increased intraluminal fluid secretion helps to soften stool and accelerate GI transit time. Lubiprostone (Amitiza) was first approved in 2006 for “chronic idiopathic constipation in adults” at a recommended dose of one 24 mg capsule twice daily with food. In 2008, Lubiprostone also received FDA approval for treatment of patients with constipation-predominant irritable bowel syndrome (IBS-C). Clinical trials have shown a significant increase in spontaneous bowel movements in patients treated with lubiprostone versus placebo as well as improvement in straining, stool consistency, and overall constipation severity. For most patients, bowel movements occur within 24 to 48 hours of lubiprostone administration. Common adverse effects include headache (13%), diarrhea, and nausea. Because of its high cost (especially relative to other available laxative agents) and lack of comparative data with other laxative therapies, lubiprostone will likely be reserved for patients with chronic constipation that fail conventional first-line agents.

**Prucalopride**

Prucalopride is a selective 5 hydroxytryptamine-4 (5HT-4) receptor agonist being developed for treatment of chronic constipation and IBS-C. Prucalopride demonstrates proenterokinetic effects (increased colonic motility and transit), specifically in the GI tract. Prucalopride, however, is more selective than the previously available serotonergic agonist cisapride and tegaserod with higher affinity for the 5HT-4 receptor. Receptor selectivity is thought to improve the safety profile of prucalopride over cisapride and tegaserod, which were removed from the market due to concerns for adverse cardiovascular events. In clinical trials, prucalopride significantly increased the number of complete, spontaneous bowel movements in adults with chronic constipation. Constipation symptoms and quality of life were also improved with prucalopride. This agent has been safely tolerated in clinical trials with no adverse cardiovascular effects versus placebo (though data are limited). Prucalopride has not yet been approved by the FDA.

**Opioid-Receptor Antagonists**

Alvimopan (Entereg) is an oral gastrointestinal-specific mu-receptor antagonist approved for short-term use in hospitalized patients to accelerate recovery of bowel function after large or small bowel resection. Causes of postoperative ileus are multifactorial, with the effects of opioids considered to be a significant contributing factor. Alvimopam antagonizes the GI (peripheral) effects of opioids without affecting analgesia because it does not cross the blood-brain barrier. Alvimopan is only available through a special use program (ENTEREG access support and education; EASE), which requires hospitals to register and meet all requirements before the drug can be administered. Additionally, alvimopan is contraindicated in patients receiving therapeutic doses of opioids for more than seven consecutive days prior to surgery (as they may be more sensitive to the drug’s effects). Dosing for alvimopan is as follows: 12 mg capsule administered 30 min to 5 hours before surgery and then 12 mg twice daily for up to 7 days or until discharge (maximum of 15 doses).

Methylnaltrexone (Relistor) is mu receptor-antagonist approved for opioid-induced constipation in patients with advanced disease receiving palliative care or when response to laxative therapy has been insufficient. This agent does not cross the blood-brain barrier or antagonize analgesia; it acts on peripheral mu receptors to antagonize unwanted opioid side effects such as constipation. It is administered at a weight-based dose as a subcutaneous injection, usually every other day (no more than once daily), and is contraindicated in patients with known or suspected gastrointestinal obstruction.

Naltrexone and naloxone are opioid antagonists but are not used in constipation because they do cross the blood-brain barrier and reverse CNS effects of opioids (respiratory depression and analgesia).

**Other Agents**

Tap-water enemas may be used to treat simple constipation. The administration of 200 mL of tap water by enema to an adult often results in a bowel movement within 30 minutes. Soap-suds enemas are no longer recommended as their use may result in proctitis or colitis.
Clinical Presentation of Irritable Bowel Syndrome

For certain groups of patients, such as those recovering from myocardial infarction or rectal surgery, straining at defecation is to be avoided. The basis of preventive therapy in these patients should be bulk-forming laxatives. Additionally, the use of docusate is popular, although its effectiveness is debated. In pregnant patients, constipation may result because of alterations in anatomy or iron supplementation. As described earlier, bulk-forming laxatives and docusates should be the first line of prevention.

LAXATIVE ABUSE SYNDROME

Misconceptions about normal bowel patterns and the effect of laxatives have contributed to a syndrome of laxative abuse that is relatively common in the United States. The availability of laxatives over the counter and as chocolates or gums conveys to the public that the use of these agents is without adverse consequences. Abuse of laxatives has occurred traditionally in persons trying to maintain daily bowel function, but has extended to others who use laxatives for the purpose of controlling weight. In either case, the consistent abuse of strong laxatives and cathartics may lead to serious illness.

Laxative abuse for the purpose of maintaining daily bowel function begins with misconceptions about the frequency, quantity, or consistency of stools. With the use of strong purgatives, the colon may be so thoroughly cleansed that a bowel movement may not occur normally until a few days later. This delay reinforces the need for more purgatives, and the cycle of laxative dependence is begun. Eventually the patient may require daily laxatives to maintain bowel function. A variation of laxative abuse is seen in persons who use them as a means of weight loss.

The laxative abuser may present with contradictory findings of diarrhea and weight loss. In addition, long-term abusers of laxatives tend to have vomiting, abdominal pain, lassitude, weakness, thirst, edema, and bone pain (caused by osteomalacia). With prolonged use of laxatives a number of serious illnesses may arise, including fluid and electrolyte imbalances (e.g., acid-base imbalances and hypokalemia), protein-losing gastroenteropathy with hypoproteinemia, and syndromes resembling colitis.

The determination of laxative abuse syndrome can be difficult because many laxative abusers vigorously deny laxative use. Middle-aged women tend to be the most common laxative abusers. The chronic laxative abuse problem should be addressed by a combination of measures, including psychiatric evaluation, dietary modification with reliance on bulk-forming laxatives, and specific guidelines to the patient for the withdrawal of stimulant laxatives.

EVALUATION OF THERAPEUTIC OUTCOMES

The ultimate goal of treatment for constipation is alteration of lifestyle (particularly diet) and modifiable secondary causes (drugs, etc.) to prevent further episodes of constipation. Short-term goals include alleviation of acute constipation with relief from symptoms. For patients with chronic constipation, the goals are more long term and include use of proper diet and decreased reliance on laxatives in addition to relief of symptoms for the patient so that quality of life is not diminished. Effective treatment of constipation requires the patient to become more knowledgeable about the causes of constipation, proper diet, and appropriate use of laxatives.

IRRITABLE BOWEL SYNDROME

IBS is a gastrointestinal syndrome characterized by chronic abdominal pain and altered bowel habits in the absence of any organic cause. It is the most commonly diagnosed gastrointestinal condition.

EPIDEMIOLOGY

The prevalence of IBS is approximately 10% to 15% based on North American and European population-based studies; however, there is a wide variation in prevalence by individual country. IBS affects men and women, young patients, and the elderly with an overall 2:1 female predominance in North America. However, younger patients and women are more likely to be diagnosed with IBS. Although only 15% of those affected actually seek medical attention, IBS is the cause of between 25% and 50% of all referrals to gastroenterologists.

PATHOPHYSIOLOGY

Although the exact pathophysiologic abnormalities with IBS are still being actively investigated, IBS likely results from altered somatovisceral and motor dysfunction of the intestine from a variety of causes. Abnormal central nervous system processing of afferent signals may lead to visceral hypersensitivity, with the specific nerve pathway affected determining the exact symptomatology expressed. This visceral hypersensitivity is a neuroenteric phenomenon that is independent of motility and psychological disturbances. Factors known to contribute to these alterations include genetics, motility factors, inflammation, colonic infections, mechanical irritation to local nerves, stress, and other psychological factors.

Serotonin-Type Receptors

The enteric nervous system contains a significant percentage of the body’s 5-hydroxytryptamine (serotonin, 5-HT). Two types of serotonin exist within the gut: serotonin type 3 (HT₃) and serotonin type 4 (HT₄), which are responsible for secretion, sensitization, and motility. There is an increase in the postprandial levels of 5-HT in those who suffer from diarrhea-predominant IBS when compared with nonsufferers. Therefore, stimulation and antagonism of these serotonin receptors have become a focused area for research on new drug therapies for both diarrhea- and constipation-predominant disease.

CLINICAL PRESENTATION

IBS presents as either diarrhea-predominant or constipation-predominant disease and can be defined as lower abdominal pain, disturbed defecation (constipation, diarrhea, or an alternating pattern of both), and bloating in the absence of structural or biochemical factors that might explain these symptoms (Table 43–12).

Because IBS can consist of a variable number of signs and symptoms, two diagnostic criteria “check lists” are commonly used to aid in the workup of a patient suspected of having IBS. The Manning criteria were first proposed in 1978, whereas the Rome criteria were initially proposed in 1999 and revised as recently as 2006 by an international working group in an effort to help standardize the diagnostic criteria used in clinical research protocols. Table 43–13 shows the symptom criteria for both of the Manning and Rome III symptom-based criteria.

Additional diagnostic steps that can be taken include sigmoidoscopy or colonoscopy; examination of the stool for occult blood and ova and parasites; complete blood cell count; erythrocyte sedimentation rate; and serum electrolytes. In some cases, radiographic imaging studies, such as computed tomography scans or barium swallows or enemas, may also be necessary if the findings of the foregoing assessment are not typical for IBS.

### TABLE 43-13 Symptom-Based Criteria for Irritable Bowel Syndrome

**The Manning criteria**
- Chronic or recurrent abdominal pain for at least 6 months and two or more of the following:
  1. Abdominal pain relieved with defecation
  2. Abdominal pain associated with more frequent stools
  3. Abdominal pain associated with looser stools
  4. Abdominal distension
  5. Feeling of incomplete evacuation after defecation
  6. Mucus in stools

**Rome III diagnostic criteria for irritable bowel syndrome**
- Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months associated with two or more of the following:
  1. Relieved with defecation
  2. Onset associated with a change in frequency of stool
  3. Onset associated with a change in form (appearance) of stool

### TREATMENT

## Irritable Bowel Syndrome

### GENERAL APPROACH TO TREATMENT

The treatment approach to IBS is based upon the predominant symptoms and their severity (Fig. 43–3). Milder, less frequent episodes can be managed with dietary restrictions and a higher-fiber diet, with addition of bulk-forming laxatives, if necessary. More persistent disease may require as-needed uses of various antispasmodic or anti-diarrheal agents such as loperamide. Lastly, the most-severe forms of this disease may call for pharmacologic agents directed specifically at the underlying neurohormonal imbalance, such as the 5-HT₄ agonists (e.g., tegaserod), or the 5-HT₃ receptor antagonists (e.g., alosetron).

Alosetron, a 5-HT₃ receptor antagonist, was withdrawn from the U.S. market in 2000 as a result of serious adverse effects, including severe constipation and ischemic colitis that did not appear in the initial clinical trials. It was reintroduced in 2002 and is now limited to an FDA-approved restricted-use program in lower initial doses, and requires extensive postmarketing surveillance. Results of these trials are necessary to definitively determine alosetron’s true safety profile, especially with regard to its association with or causation of fatal ischemic colitis.

### CONSTITUTION-PREDOMINANT DISEASE

In the constipation-predominant patient, dietary fiber may be beneficial. Patients should be instructed to begin with 1 tablespoonful of fiber with one meal daily and gradually increase the dose to include fiber with two and three meals a day until the desired outcome is achieved. End points that the patient should aim for include bulkier and more easily passed stools. For patients unable to tolerate dietary bran, bulking agents such as psyllium may be substituted. Laxative use is not encouraged in these patients, and it should only be used in the smallest dose for the least amount of time in cases of severe constipation.

The 5-HT₃ partial agonist tegaserod was the first therapy approved by the FDA specifically for short-term, intermittent treatment of IBS-C. Tegaserod was suspended from marketing in early 2007 at the request of the FDA due to an analysis of clinical trial data showing a small, yet significant, increase in ischemia events (MI, cerebrovascular accident (CVA), and unstable angina) in patients with preexisting cardiovascular disease and/or cardiovascular risk factors. In July 2007, the drug’s manufacturer, Novartis, began a tegaserod (Zelnorm) restricted-access program for patients in the United States. Tegaserod is a serotonin derivative that activates 5-HT₃ receptors on the neurons in the gastrointestinal tract, increasing GI motility and decreasing visceral sensations. It is approved as 2 mg or 6 mg doses given twice...
daily 30 minutes prior to a meal with water for up to 12 weeks. Stimulation of the 5-HT3 receptor by tegaserod increases gastric secretions and promotes motility, with improvement in symptoms generally occurring within the first week of therapy. Currently this therapy is only approved for use in women; efficacy and safety in men have not been established because of inadequate numbers of men enrolled in clinical trials to date. Diarrhea was the most common adverse effect, resulting in drug discontinuation in 1.6% of study subjects.

**CLINICAL CONTROVERSY**

The newer serotonin receptor agonists and antagonists tegaserod and alosetron act on GI-specific serotonin receptors to treat constipation-predominant and diarrhea-predominant IBS, respectively. However, both drugs are currently only indicated for women. Efficacy and safety in men have not been established because the initial manufacturer’s sponsored clinical trials contained insufficient numbers of men with IBS to provide the necessary statistical power to prove efficacy and safety. Ongoing studies should determine whether these drugs are indicated in men.

## DIARRHEA-PREDOMINANT DISEASE

For patients in whom diarrhea is the primary complaint, avoidance of certain food products may be necessary. Caffeine, alcohol, and artificial sweeteners (sorbitol, fructose, and mannitol) are known to irritate the gut and produce a laxative effect. Lactose intolerance should be considered in certain patients; however, the prevalence of this condition may be exaggerated.

Herbal medicines or teas often contain senna, which may produce diarrhea. In patients with disease persistence following dietary modification, loperamide may be used for episodic management of urgent diarrhea, or in situations in which the patient wishes to avoid the possibility of an acute onset of symptoms. Loperamide decreases intestinal transit, enhances water and electrolyte absorption, and strengthens rectal sphincter tone. Some patients may require continuous therapy, and careful dosage titration can usually be undertaken to prevent the development of constipation.

Diarrhea-predominant IBS caused by excessive stimulation of the 5-HT3 receptor can be relieved by the drug alosetron. Alosetron was the first effective treatment for diarrhea-predominant IBS. However, in November 2000 it was voluntarily withdrawn from the market because of severe GI adverse effects, including 113 reported cases of serious constipation and 8 cases of possible ischemic colitis and death. This decision was met with a great public outcry, as many who had suffered for years had experienced relief for the first time. Because this drug was highly effective in many patients, the FDA approved restricted use of alosetron in June 2002. Alosetron is now available via an FDA-approved restricted-use program in conjunction with GlaxoSmithKline as detailed at [http://www.lotronex.com](http://www.lotronex.com). It is now indicated, in lower initial doses of 0.5 mg twice daily, for women with diarrhea-predominant symptoms of longer than 6 months’ duration that are not relieved by conventional therapy. Healthcare providers must use extreme caution in therapy with this drug and must follow strict FDA-mandated guidelines.

Probiotics (see earlier Diarrhea) such as *Lactobacillus* and *Bifidobacterium* reduced IBS symptoms in several investigative trials. Another 5-HT3 antagonist, cilansetron, has demonstrated efficacy similar to that of alosetron in phase II trials and enrolled enough male patients to show benefit in males as well.

**Use of Antidepressants in Irritable Bowel Syndrome**

Tricyclic antidepressants have shown some benefit in treatment of diarrhea-predominant IBS associated with moderate to severe abdominal pain, by modulating perception of visceral pain, altering GI transit time, and treating underlying comorbidities. Selective serotonin reuptake inhibitors are less-well studied, with only one report with paroxetine showing some improvement in stool passage and “well-being” but no decrease in abdominal pain.

Figure 43–3 shows a general stepwise approach to the management of both constipation and diarrhea-predominant IBS.

### PAIN IN IRRITABLE BOWEL SYNDROME

Some patients with IBS suffer significant pain associated with their disease. Data supporting the use of antispasmodic agents in these patients are conflicting. A trial of low-dose antidepressant therapy is indicated, especially if pain is associated with eating. Both tricyclic antidepressants and serotonin reuptake inhibitors produce analgesia and may relieve depressive symptoms if present. Preprandial doses of drugs containing anticholinergic properties may suppress pain (and/or diarrhea) associated with an overactive postprandial gastrocolonic response. Tricyclic antidepressants should be avoided in patients with pain and constipation. In addition, psychotherapy, including cognitive behavioral therapy, relaxation therapy, and hypnotherapy, has been shown to decrease IBS symptoms.

### EVALUATION OF THERAPEUTIC OUTCOMES

IBS is usually classified as constipation-predominant, diarrhea-predominant, or IBS with abdominal pain and bloating. Therapeutic goals in IBS should focus on the patient’s primary complaint. Dietary and drug therapy goals should focus on end-organ treatment to relieve abdominal pain (antispasmodic drugs) or disturbed bowel habits (antidiarrheals and bulk-forming agents). Additionally, severe symptoms from central nervous system dysregulation should be treated with antidepressants, psychotherapy, relaxation/stress management, cognitive behavior treatment, and/or hypnosis aimed at specific affective disorders. Lastly, the serotonin receptor agonists and antagonists can be used in carefully selected patients whose symptoms are not adequately controlled with other agents. The American Gastroenterology Association recommends that patients with severe IBS consider psychological treatments such as psychotherapy, relaxation/stress management, and/or cognitive behavior treatment.

### ABBREVIATIONS

AGA: American Gastroenterology Association
AIDS: acquired immunodeficiency syndrome
CDC: Centers for Disease Control and Prevention
CVA: Cerebrovascular Accident
5-HT: serotonin
IBS: irritable bowel syndrome
IBS-C: constipation-predominant irritable bowel syndrome
KEY CONCEPTS

1. Cirrhosis is a severe, chronic, irreversible disease associated with significant morbidity and mortality. However, the progression of cirrhosis secondary to alcohol abuse can be interrupted by abstinence. It is therefore imperative for the clinician to educate and support abstinence from alcohol as part of the overall treatment strategy of the underlying liver disease.

2. Patients with cirrhosis should receive endoscopic screening for varices, and certain patients with varices should receive primary prophylaxis with nonselective β-adrenergic blockade therapy to prevent variceal hemorrhage.

3. When nonselective β-adrenergic blocker therapy is used to prevent rebleeding, β-blocker therapy can be titrated to achieve a goal heart rate of 55 to 60 beats per minute or the maximal tolerated dose.

4. Octreotide is the preferred vasoactive agent for the medical management of variceal bleeding. Endoscopy employing endoscopic band ligation is the primary therapeutic tool for the management of acute variceal bleeding.

5. The combination of spironolactone and furosemide is the recommended initial diuretic therapy for patients with ascites.

6. All patients who have survived an episode of spontaneous bacterial peritonitis should receive long-term antibiotic prophylaxis.

7. The mainstay of therapy of hepatic encephalopathy involves therapy to lower blood ammonia concentrations and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose.

Chronic liver injury causes damage to normal liver tissue resulting in the development of regenerative nodules surrounded by fibrous bands. Fibrosis, defined as the encapsulation or replacement of injured tissue by collagenous scar, results from an abnormal perpetuation of the normal wound healing process. If fibrotic liver disease advances, collagen bands progress to bridging fibrosis and eventually frank hepatic cirrhosis. The word cirrhosis is derived from the Greek kirrhos, meaning orange-yellow, and refers to the color of the cirrhotic liver as seen upon autopsy or during surgery. Cirrhosis is an advanced stage of liver fibrosis. The advanced fibrosis of cirrhosis leads to shunting of the portal and arterial blood supply directly into hepatic outflow through the central veins, and exchange between hepatic sinusoids and hepatocytes is compromised. Clinical consequences of cirrhosis include impaired hepatocyte function, the increased intrahepatic resistance of portal hypertension, and hepatocellular carcinoma. Circulatory irregularities such as splanchic vasodilation, vasoconstriction and hypoperfusion of the kidneys, water and salt retention, and increased cardiac output also occur.

While cirrhosis has many causes (Table 44–1), in the Western world, excessive alcohol intake and hepatitis C are the most common causes. This chapter elucidates the pathophysiology of cirrhosis and the resultant effects on human anatomy and physiology. Treatment strategies for managing the most commonly encountered clinical complications of cirrhosis are discussed.

EPIDEMIOLOGY

The exact prevalence of cirrhosis is unknown, but a reasonable estimate is that 1% of populations have histologically diagnosable cirrhosis. Cirrhosis was responsible for over 28,000 deaths in America in 2007, and chronic liver disease continues to be ranked twelfth among the leading causes of death in the United States. Acute variceal bleeding and spontaneous bacterial peritonitis are among the immediately life-threatening complications of cirrhosis. Associated conditions causing significant morbidity include ascites and hepatic encephalopathy. Approximately 50% of patients with cirrhosis develop ascites during 10 years of observation and, within 2 years, nearly half of patients who develop ascites will die.

SECTION 4

Gastrointestinal Disorders

PATHOPHYSIOLOGY OF CIRRHOSIS

Any discussion of cirrhosis must be based on a firm understanding of hepatic anatomy and vascular supply. Conceptually, the liver can be thought of as an elaborate blood filtration system receiving blood from the hepatic artery and the portal vein, which are lined by the workhorses of the liver, the hepatocytes. Individual hepatocytes are arranged in plates that are one cell thick. The six or more surfaces of each individual hepatocyte make contact with adjacent hepatocytes, border the bile canaliculi, or are exposed to the sinusoidal space. Filtered blood travels into the terminal hepatic venules, also called central veins, and then empties into larger hepatic veins and eventually into the inferior vena cava. Functional gradients of hepatocytes based on oxygen saturation have been reported. Hepatocytes closest to the portal triad, which contains branches of the portal vein and hepatic artery, bile ducts, and lymphatic and nerve tissue. It then drains through the sinusoidal spaces (also known as the space of Disse) of the hepatic lobule, which are lined by the workhorses of the liver, the hepatocytes. Individual hepatocytes are arranged in plates that are one cell thick. The six or more surfaces of each individual hepatocyte make contact with adjacent hepatocytes, border the bile canaliculi, or are exposed to the sinusoidal space. Filtered blood travels into the terminal hepatic venules, also called central veins, and then empties into larger hepatic veins and eventually into the inferior vena cava. Functional gradients of hepatocytes based on oxygen saturation have been reported. Hepatocytes closest to the portal triad, which contains the hepatic artery, have twice the oxygen saturation of those hepatocytes nearer to the terminal hepatic venule. Those hepatocytes closest to the portal triad also have higher levels of peroxisomes, glucose-6-phosphatase activity, urea cycle activity, bile acid uptake, glutathione content, and glycogen synthesis.

Normally, hepatic stellate cells function to store vitamin A and help to maintain the normal matrix in the sinusoidal space. During chronic liver disease, however, hepatic stellate cells undergo an "activation" process, which is the central event in the development of hepatic fibrosis. Activation causes stellate cells to lose vitamin A, become highly proliferative, and synthesize fibrotic scar tissue, which accumulates in the sinusoidal space. This leads to loss of hepatocyte microvilli, loss of sinusoidal endothelial fenestrae, deterioration of hepatocyte function, and, if fibrosis progresses, eventual cirrhosis.

Cirrhosis causes changes to the splanchnic vascular bed as well as the systemic circulation. Splanchnic vasodilation, decreased responsiveness to vasoconstrictors, and the formation of new blood vessels contribute to an increased splanchnic blood flow, formation of gas-troesophageal varices, and variceal bleeding. All of these components are part of the portal hypertensive syndrome. Portal hypertension is characterized by hypervolemia, increased cardiac index, hypotension, and decreased systemic vascular resistance. This is a so-called hyperkinetic syndrome, which leads to a marked activation of neurohumoral vasoactive factors, a response that occurs in an effort to maintain the arterial blood pressure within normal limits. Activation of neurohumoral vasoactive factors is a main component in the pathophysiology of the ascites and renal dysfunction that often accompany chronic liver disease. Portal-systemic shunting may also occur and is involved in hepatic encephalopathy and other complications.

In summary, cirrhosis results from fibrotic changes within the hepatic sinusoids and results in changes in the levels of vasodilatory and vasoconstrictor mediators and an increase in blood flow to the splanchnic vasculature.

FIGURE 44-1. The portal venous system.

ANATOMIC AND PHYSIOLOGIC EFFECTS OF CIRRHOSIS

Cirrhosis and the pathophysiologic abnormalities that cause it result in the commonly encountered problems of ascites, portal hypertension, esophageal varices, hepatic encephalopathy, and coagulation disorders. Other less commonly seen problems in patients with cirrhosis include hepatorenal syndrome, hepatopulmonary syndrome, and endocrine dysfunction. These are discussed in the section dealing with the management of cirrhotic complications.

ASCITES

Ascites is the accumulation of an excessive amount of fluid within the peritoneal cavity. It is the most commonly occurring major complication of cirrhosis. Approximately half of all cirrhotic patients develop ascites within 10 years of diagnosis. Several hypotheses have been offered to explain the mechanism for the development of ascites in decompensated cirrhosis. Most acceptable theories state that ascites formation begins as a result of the development of sinusoidal hypertension and portal hypertension. Portal hypertension activates vasodilatory mechanisms that are mediated mostly by nitric oxide overproduction. This leads to splanchnic and peripheral arteriolar vasodilation and, in advanced disease, a drop in arterial pressure. Baroreceptor-mediated activation of the renin-angiotensin-aldosterone system, activation of the sympathetic nervous system, and release of antiuretic hormone occur in response to the resulting arterial hypotension in an effort to restore normal blood pressure. These changes cause renal sodium and water retention. Additionally, ongoing splanchnic vasodilation increases splanchnic lymph production beyond the capacity of the lymph transportation system. Leakage of lymphatic fluid into the peritoneal cavity occurs. Persistent renal sodium and water retention, increased splanchnic vascular permeability, and lymph leakage into the peritoneal cavity combine to create the sustained ascites formation of end-stage liver disease.

PORTAL HYPERTENSION AND VARICES

Sinusoidal portal hypertension is most often caused by alcohol-induced cirrhosis. It is associated with acute variceal bleeding, a medical emergency that carries a mortality rate of 20% at 6 weeks and is among the most severe complications of cirrhosis. Portal
Portal Hypertension and Cirrhosis

CHAPTER 44

Portal hypertension is defined by the presence of a gradient of greater than 5 mmHg between the portal and central venous pressures (see Fig. 44–1). The gradient is called the hepatic venous pressure gradient (HVPG). Esophageal and gastric varices arise after the pressure gradient of 8 to 10 mm Hg is reached, and bleeding can occur from these varices once the gradient rises above 12 mmHg. Varices occur because of the body’s need to find collateral outlets to relieve the increased pressure of portal hypertension. Other outlets, besides esophageal and gastric varices, include retroperitoneal vessels, the hemorrhoidal venous plexus, a recanalized umbilical vein, and intrahepatic shunts. Five percent of patients with cirrhosis are expected to develop varices within 1 year, and 28% will develop them within 3 years. Acute variceal bleeding occurs in 25% to 40% of cirrhosis patients and is the cause of death for one third of these patients.

Progression to bleeding can be predicted by Child-Pugh score, red wale markings on the varices, and an alcoholic etiology of liver disease. Twelve percent of patients with small varices at initial endoscopy will experience variceal bleeding within 2 years. Twenty to 29% of patients with variceal bleeding will die within 30 days. Rebleeding is common following initial hemorrhage, especially within the first 72 hours. More than 50% of recurrent bleeding episodes occur within the first 10 days of the initial bleed, and risk returns to baseline after 6 weeks. Primary prevention of bleeding is a major goal in the therapy of portal hypertension, and strategies include both pharmacologic and surgical approaches.

HEPATIC ENCEPHALOPATHY

The term hepatic encephalopathy (HE) describes a wide range of neuropsychiatric symptoms that are associated with liver failure. Symptoms of HE are thought to result from an accumulation of gut-derived nitrogenous substances in the systemic circulation as a consequence of decreased hepatic functioning and shunting through portosystemic collaterals bypassing the liver. Once these substances enter the central nervous system, they cause alterations of neurotransmission that affect consciousness and behavior. Ammonia is the most commonly cited culprit in the pathogenesis of HE, but glutamate, benzodiazepine receptor agonists, and manganese are also potential causes. Arterial ammonia levels are increased commonly in both acute and chronic liver disease, but an established correlation between blood ammonia levels and mental...
status does not exist.\textsuperscript{14} Despite this, interventions to lower blood ammonia levels remain the mainstay of treatment for HE.

HE is now categorized as type A, B, or C based on nomenclature developed by the 11th World Congress of Gastroenterology.\textsuperscript{15} Type A is HE induced by acute liver failure, Type B is due to portal-systemic bypass without associated intrinsic liver disease, and type C is HE that occurs in patients with cirrhosis. The duration and characteristics of HE are classified as episodic, persistent, and minimal. Episodic HE occurs spontaneously or is precipitated by a clinical factor, such as gastrointestinal bleeding. Recurrent HE is defined by two episodes of spontaneous or precipitated HE occurring within 1 year, and the hallmark of persistent HE is chronic cognitive deficits that decrease a patient’s quality of life. Minimal HE refers to cirrhotic patients who do not suffer clinically overt cognitive dysfunction but who are found to have cognitive impairment on psychological studies. The onset of HE in a patient with liver failure may be related to the presence of several known precipitating factors. In cases of HE associated with a precipitant, if that precipitant can be cured or discontinued, it may also be possible to discontinue treatment for HE. In many cases, no precipitant is found and, therefore, long-term treatment of HE may be required.

### COAGULATION DEFECTS

The liver synthesizes most of the proteins that are responsible for the maintenance of hemostasis (the balance between coagulation and anticoagulation).\textsuperscript{15} Hepatocellular damage can lead to a disruption in hemostasis because of defects it may cause in the function of coagulation and fibrinolytic factors. These defects include a reduction in the synthesis of clotting factors, excessive fibrinolysis, disseminated intravascular coagulation, thrombocytopenia, and platelet dysfunction. Most coagulation factors are created in the liver, and the levels of these factors can be significantly reduced in chronic liver disease associated with extensive hepatocellular damage. Factor VII is the first factor to decrease as liver function declines due to its short half-life. A reduction in clotting factor VII is common in end-stage liver disease, affecting 60% of patients. Low factor VII activity is prognostic for reduced survival, and the prothrombin time is a standard component of the Child-Pugh scoring system. Accelerated intravascular coagulation and fibrinolysis can be detected in some patients with cirrhosis. The coexistence of sepsis, shock, surgery, trauma, or ascites may cause a progression from accelerated intravascular coagulation to disseminated intravascular coagulation. In patients with cirrhosis, disseminated intravascular coagulation involves increased release of procoagulants, impaired removal of activated coagulation factors and endotoxins produced by gut bacteria, and reduced synthesis of coagulation inhibitors. Both platelet number and function may also be affected in cirrhosis. Platelet numbers are reduced by multiple mechanisms, including splenomegaly due to portal hypertension and sequestration of platelets in the spleen, reduced hepatic production of thrombopoietin, bone marrow suppression, and increased platelet destruction. Mild to moderate thrombocytopenia occurs in 15% to 70% of patients with cirrhosis. The net effect of the coagulation disorders that occur in cirrhosis is the development of bleeding.

### CLINICAL PRESENTATION

Cirrhotic patients may present in a variety of ways, from asymptomatic with abnormal radiographic or laboratory studies to decompensated with ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, or variceal bleeding.\textsuperscript{16}

### CLINICAL PRESENTATION OF CIRRHOSIS

#### Signs and Symptoms
- Asymptomatic
- Hepatomegaly, splenomegaly
- Pruritus, jaundice, palmar erythema, spider angiomata, hyperpigmentation
- Gynecomastia, reduced libido
- Ascites, edema, pleural effusion, and respiratory difficulties
- Malaise, anorexia, and weight loss
- Encephalopathy

#### Laboratory Tests
- Hypoalbuminemia
- Elevated prothrombin time
- Thrombocytopenia
- Elevated alkaline phosphatase
- Elevated aspartate transaminase (AST), alanine transaminase (ALT), and γ-glutamyl transpeptidase (GGT)

The approach to a patient with suspected liver disease begins with a thorough history and physical exam. Some presenting characteristics of patients with cirrhosis include anorexia, weight loss, weakness, fatigue, jaundice, pruritis, gastrointestinal bleeding, coagulopathy, increasing abdominal girth with shifting flank dullness, mental status changes, and vascular spiders. Osteoporosis, as a result of vitamin D malabsorption and resultant calcium deficiency, can also occur.

A thorough history including risk factors that predispose patients to cirrhosis should be taken.\textsuperscript{19} Quantity and duration of alcohol intake should be determined. Risk factors for hepatitis B and C transmission should be inquired about. These include birthplace in endemic areas, sexual history, intranasal or intravenous drug use, body piercing or tattooing, and accidental contamination of body tissues or blood. Information concerning any history of transfusions, as well as any personal history of autoimmune or hepatic diseases, should be gathered. A family history should also be taken, looking especially for any family member with a prior history of autoimmune or hepatic diseases.

### LABORATORY ABNORMALITIES

There are no laboratory or radiographic tests of hepatic function that can accurately diagnose cirrhosis.\textsuperscript{16} Despite this, liver function tests, a complete blood count with platelets, and a prothrombin time test should be performed if liver disease is suspected. Tests that measure the level of serum liver enzymes are usually referred to as liver function tests.\textsuperscript{17} However; these tests actually reflect hepatocyte integrity or cholestasis, not liver function.

Routine liver tests include alkaline phosphatase, bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), and γ-glutamyl transpeptidase (GGT). Additional markers of hepatic synthetic activity include albumin and prothrombin time. Liver function tests are often the first step in the evaluation of patients who present with symptoms or signs suggestive of cirrhosis.\textsuperscript{19} The use of liver function tests in the diagnosis and management of cirrhosis is discussed in the following sections. It may be useful to group the tests into two broad categories: markers of hepatocyte integrity such as the transaminases and markers of liver function mass such as prothrombin time and albumin.\textsuperscript{17}

#### Aminotransferases

The aminotransferases, AST and ALT, are enzymes that are highly concentrated in the liver. Liver injury, whether acute or chronic,
describes a general algorithm for the interpreta-
tion livers for transplantation. 20 The Child-Pugh classification
the United Network for Organ Sharing (UNOS) in the alloca-
scoring system is now the accepted classification scheme used by
Pugh score. The newer Model for End-stage Liver Disease (MELD)
failure, when available, are normally based upon the Child-
ratios greater than one.

Kaplan had ratios greater than two, whereas 92% of patients had
in patients with suspected alcoholic liver disease. Seventy percent
in the study by Cohen and

The Child-Pugh classification system has gained widespread accep-
tance as a means of quantifying the myriad effects of the cirrhotic
process on the laboratory and clinical manifestations of this
disease.19 Recommended drug dosing adjustments for patients in
liver failure, when available, are normally based upon the Child-
Pugh score. The newer Model for End-stage Liver Disease (MELD)
scoring system is now the accepted classification scheme used by
the United Network for Organ Sharing (UNOS) in the allocation
livers for transplantation.20 The Child-Pugh classification system employs a combination of physical and laboratory find-
ings (Table 44–2), whereas the MELD score calculation takes into account a patient’s serum creatinine, bilirubin, international
normalized ratio (INR), and etiology of liver disease omitting the more subjective reports of ascites and encephalopathy used
in the Child-Pugh system. The MELD scoring calculation is as follows:21

\[
\text{MELD score} = 0.957 \times \log (\text{creatinine mg/dL}) + 0.378 \times \log (\text{bilirubin mg/dL}) \\
+ 1.120 \times \log (\text{INR}) + 0.643^* 
\]

These classification systems are important because they are used to assess and define the severity of the cirrhosis, and as a predictor for patient survival, surgical outcome, and risk of variceal bleeding.

**Alkaline Phosphatase and Gamma-Glutamyl Transpeptidase**

Elevated serum levels of alkaline phosphatase and GGT occur in cases of liver injury with a cholestatic pattern and therefore accompany conditions such as primary biliary cirrhosis, primary sclerosing cholangitis, drug-induced cholestasis, bile duct obstruction, autoimmune cholestatic liver disease, and metastatic cancer of the liver.21 Neither alkaline phosphatase nor GGT is found solely in the liver, and elevations in either of these biomarkers can occur in a variety of disease states affecting other bodily tissues. However, the combination of an elevation in alkaline phosphatase level with a concomitant elevation in GGT level increases clinical suspicion of hepatic etiology.

**Child-Pugh Classification and Model for End-Stage Liver Disease Score**

The Child-Pugh classification system has gained widespread accept-
tance as a means of quantifying the myriad effects of the cirrhotic
process on the laboratory and clinical manifestations of this
disease.19 Recommended drug dosing adjustments for patients in
liver failure, when available, are normally based upon the Child-
Pugh score. The newer Model for End-stage Liver Disease (MELD)
scoring system is now the accepted classification scheme used by
the United Network for Organ Sharing (UNOS) in the allocation
livers for transplantation.20 The Child-Pugh classification system employs a combination of physical and laboratory find-
ings (Table 44–2), whereas the MELD score calculation takes into account a patient’s serum creatinine, bilirubin, international
normalized ratio (INR), and etiology of liver disease omitting the more subjective reports of ascites and encephalopathy used
in the Child-Pugh system. The MELD scoring calculation is as follows:21

\[
\text{MELD score} = 0.957 \times \log (\text{creatinine mg/dL}) + 0.378 \times \log (\text{bilirubin mg/dL}) \\
+ 1.120 \times \log (\text{INR}) + 0.643^* 
\]

These classification systems are important because they are used to assess and define the severity of the cirrhosis, and as a predictor for patient survival, surgical outcome, and risk of variceal bleeding.

**Bilirubin**

Bilirubin is the product of the breakdown of hemoglobin mole-
cules in the reticuloendothelial system.21 Elevations in serum
congested bilirubin indicate that the liver has lost at least half of its excretory capacity and are usually a sign of liver disease. When found in conjunction with markedly elevated AST and ALT, congested hyperbilirubinemia indicates the possible presence of acute viral hepatitis, autoimmune hepatitis, toxic liver injury, or ischemic liver injury. Elevated congested bilirubin levels with concomitant increases in alkaline phosphatase and normal ami-
otransferase levels are a sign of cholestatic disease and possible cholestatic drug reactions. Causes of elevations in uncongested bilirubin include hemolysis, Gilbert syndrome, hemato ma reabsorption, and ineffective erythropoiesis. Causes of congested hyperbilirubinemia include bile duct obstruction, hepatitis, cirrhosis, primary sclerosing cholangitis, primary biliary cirrhosis, total parenteral nutrition, drug toxins, and vanishing bile duct syndrome. When cirrhosis has been established, the degree of bilirubin elevation has prognostic significance and is used as a component of the Child-Pugh and MELD scoring systems for quantifying the degree of cirrhosis.19,21

10 times normal, the etiology is likely a result of drugs or other toxins, ischemia, or acute viral hepatitis. Elevations less than 10 times normal have a broad differential. Unfortunately, most liver enzyme abnormalities will fall into a mixed pattern providing limited diagnostic assistance.

**Albumin and Coagulation Factors**

Albumin and coagulation proteins are markers of hepatic synthetic activity and are therefore used to estimate the level of hepatic functioning in cirrhosis. Albumin and prothrombin time (PT) are used in the Child-Pugh system for quantifying liver disease, and the INR is used in the MELD scoring system as a marker of coagulation. Albumin levels can be affected by a number of factors, including malnutrition, malabsorption, and protein losses from renal and intestinal sources.

Coagulation factors I, II, V, VII, VIII, IX, X, XI, XII, and XIII are synthesized in the liver, and significantly reduced levels of coagulation factors II, V, VII, and XIII have been observed in patients with chronic liver disease and systemic bleeding unrelated to portal hypertension. PT prolongation has also been observed in patients with chronic liver disease also have PT prolongation. The PT has been used in cases of acetaminophen-induced hepatic failure, viral hepatitis, and drug reactions as a prognostic laboratory value. A PT over 100 seconds correlates with poor prognosis in acetaminophen-induced hepatic failure, and over 50 seconds indicates a poor prognosis in cases of viral hepatitis and drug reactions.

**Thrombocytopenia**

Thrombocytopenia (generally defined as a platelet count less than 150,000) is a common feature of chronic liver disease found in 15% to 70% of cirrhotic patients depending on the stage of liver disease and definition of thrombocytopenia. The etiology of thrombocytopenia in liver disease is multifactorial, involving primarily splenomegaly due to portal hypertension with pooling of platelets in the spleen. A decrease in thrombopoietin due to decreased hepatic synthesis occurs as well as an immune-mediated destruction of platelets. Additionally, bone marrow suppression related to the hepatitis C virus or interferon antiviral treatment may exist and lead to thrombocytopenia associated with the cirrhotic process.

**ENDOSCOPIC AND RADIOGRAPHIC ABNORMALITIES**

While no radiographic test is considered a diagnostic standard for cirrhosis, radiographic studies may be used to detect ascites, hepatosplenomegaly, hepatic or portal vein thromboses, and hepatocellular carcinoma. Ultrasonography, because it does not require radiation exposure or intravenous contrast and is relatively low cost, should be the first radiographic study in the evaluation of a patient with suspected cirrhosis. Hepatic nodularity, irregularity, increased echogenicity, and atrophy are all ultrasonographic findings indicative of cirrhosis. Ascites may also be detected on ultrasound. Computed tomography and magnetic resonance imaging can demonstrate liver nodularity as well as atrophic and hypertrophic changes. Ascites and varices may also be detected on computed tomography or magnetic resonance imaging scans. Portal vein patency can be assessed by computer tomography imaging. Liver biopsy should be considered after a thorough noninvasive workup has failed to confirm a diagnosis in suspected cirrhosis. Liver biopsy has a sensitivity and specificity of 80% to 100% for an accurate diagnosis of cirrhosis and its etiology. The success of biopsy as a diagnostic tool is dependent upon the number of histologic samples retrieved as well as the sampling method used.

**TREATMENT**

**Cirrhosis**

**GENERAL APPROACHES TO TREATMENT**

General approaches to therapy in cirrhosis should include the following:

1. Identify and eliminate, where possible, the causes of cirrhosis (e.g., alcohol abuse).
2. Assess the risk for variceal bleeding and begin pharmacologic prophylaxis when indicated. Propylactic endoscopic therapy can be used for patients with high-risk medium and large varices as well as in patients with contraindications or intolerance to nonselective β-adrenergic blockers. Endoscopic therapy is also appropriate for patients suffering acute bleeding episodes. Variceal obliteration with endoscopic techniques in conjunction with pharmacological intervention is the recommended treatment of choice in patients with acute bleeding.
3. Evaluate the patient for clinical signs of ascites and manage with pharmacologic therapy (e.g., diuretics) and paracentesis. Careful monitoring for spontaneous bacterial peritonitis (SBP) should be used in patients with ascites who undergo acute deterioration.
4. Hepatic encephalopathy is a common complication of cirrhosis and requires clinical vigilance and treatment with dietary restriction, elimination of central nervous system depressants, and therapy to lower ammonia levels.
5. Frequent monitoring for signs of hepatorenal syndrome, pulmonary insufficiency, and endocrine dysfunction is necessary.

**DESIGNED OUTCOMES**

The desired therapeutic outcomes can be viewed in two categories: resolution of acute complications such as tamponade of bleeding and resolution of hemodynamic instability for an episode of acute variceal hemorrhage and prevention of complications through lowering of portal pressure with medical therapy using β-adrenergic blocker therapy or supporting abstinence from alcohol. Treatment end points and desired therapeutic outcomes are presented for each of the recommended therapies discussed.

**MANAGEMENT OF PORTAL HYPERTENSION AND VARICEAL BLEEDING**

The management of varices involves three strategies: (a) primary prophylaxis (prevention of the first bleeding episode); (b) treatment of acute variceal hemorrhage; and (c) secondary prophylaxis (prevention of rebleeding in patients who have previously bled).

**Primary Prophylaxis**

β-Adrenergic Blockade The mainstay of primary prophylaxis is the use of nonselective β-adrenergic blocking agents such as propranolol or nadolol. These agents reduce portal pressure by reducing portal venous inflow via two mechanisms: a decrease in cardiac output through β1-adrenergic blockade and a decrease in splanchnic blood flow through β2-adrenergic blockade.
Meta-analysis of 12 trials of the nonselective β-adrenergic blockers propranolol or nadolol demonstrated the effectiveness of these agents in the prevention of bleeding, especially in patients with medium- or large-sized varices, over a median follow-up of 2 years with a trend toward a reduction in mortality. This analysis indicated that one bleeding episode is avoided for every 10 patients treated with a nonselective β-adrenergic blocker. Mortality was lowered in cirrhotic patients with esophageal varices who have never bled when those patients are treated with a β-adrenergic blocker. In this analysis, it was found that one life was saved for every 17 patients treated with a β-adrenergic blocker. Nadolol reduces the rate of growth of small esophageal varices in patients with cirrhosis. However, β-adrenergic blocker therapy does not prevent the formation of first varices. Screening esophagogastroduodenoscopy (EGD) is recommended for the diagnosis of esophagogastric varices when the diagnosis of cirrhosis is made, repeated every 2 to 3 years in patients who have no varices upon initial surveillance, or repeated annually in the event of decompensation. Once started, β-adrenergic blocker therapy should be continued for life unless it is not tolerated.

Treatment Recommendations: Variceal Bleeding—Primary Prophylaxis

All patients with cirrhosis should be screened for varices upon diagnosis. For patients with small varices (less than 5 mm) who have not bled and who have no criteria for increased risk of bleeding (increased risk includes those with Child-Pugh score of B or C or the presence of red wale marks on varices), β-adrenergic blocker therapy may be instituted, although long-term benefit has not been established. Patients with small varices plus risk factors for variceal hemorrhage should receive prophylaxis therapy with a nonselective β-adrenergic blocker (such as propranolol). All patients found to have medium to large varices (varices greater than 5 mm) that have not bled but have high risk for hemorrhage should receive prophylaxis therapy with a nonselective β-adrenergic blocker or endoscopic varical ligation (EVL). Patients with medium and large varices who have not bled and who are at lower risk for hemorrhage should receive prophylaxis therapy with nonselective β-adrenergic blocker therapy instead of EVL; although, EVL may be used in patients who are intolerant or nonadherent or who have contraindications to β-blocker therapy. Initiate therapy with oral propranolol 20 mg twice daily or nadolol 40 mg once daily and titrate to maximal tolerated dose. In most studies, the dose of nonselective β-adrenergic blocker was titrated to decrease the heart rate by 25% of baseline. Heat rate does not correlate with reduction in HVPG, and direct HVPG measurement is not widely available; therefore, titration of β-blocker therapy to the maximal tolerated dose is now recommended.

Patients with contraindications to therapy with nonselective β-adrenergic blockers (i.e., those with asthma, insulin-dependent diabetes with episodes of hypoglycemia, and peripheral vascular disease) or intolerance to β-adrenergic blockers should be considered for alternative prophylactic therapy with EVL. EVL has been compared to nonselective β-adrenergic blocker therapy in patients with large varices and found to be associated with a significantly lower incidence of first variceal bleed. EVL is equivalent to nadolol and propranolol for prevention of first variceal bleed. Current guidelines place EVL as a possible first option for primary prophylaxis in patients with high-risk medium to large varices. EVL is the recommended secondary option for patients with lower-risk medium to large varices who are intolerant to, are nonadherent to, or have contraindications to nonselective β-adrenergic blocker therapy. Nitrates are no longer recommended as alternative therapy for primary prophylaxis against variceal bleeding in patients with intolerance to nonselective β-adrenergic blockers. In fact, isosorbide mononitrate was found in one study to result in a greater 1- and 2-year probability of first variceal bleed with no difference in survival as compared to placebo. At this time, there is also insufficient evidence to support the use of other therapies and procedures (such as combination nonselective β-adrenergic blocker therapy with isosorbide mononitrate, combination nonselective β-adrenergic blocker therapy with spironolactone, combination nonselective β-adrenergic blocker therapy with EVL, shunt surgery, and endoscopic sclerotherapy) for primary prevention of variceal hemorrhage.

Nonselective β-adrenergic blocker therapy remains the mainstay of therapy in portal hypertension patients with known varices to avoid first variceal bleeding.

**ACUTE VARICEAL HEMORRHAGE**

Variceal hemorrhage is a medical emergency that carries a mortality rate of 15% to 20%, requires admission to an intensive care unit, and is one of the most feared complications of cirrhosis. It is important to note that variceal bleeding secondary to portal hypertension can occur in patients without signs of liver disease; for example, in patients with chronic portal vein thrombosis. Treatment of acute variceal bleeding includes general stabilizing and assessment measures as well as specific measures to control the acute hemorrhage and prevent early recurrence.

**Management of Acute Variceal Hemorrhage**

Initial treatment goals include (a) adequate blood volume resuscitation, (b) protection of airway from aspiration of blood, (c) correction of significant coagulopathy and/or thrombocytopenia with fresh frozen plasma and platelets, (d) prophylaxis against SBP and other infections, (e) control of bleeding, (f) prevention of rebleeding, and (g) preservation of liver function. Prompt stabilization of blood volume with a goal of maintaining hemodynamic stability and a hemoglobin of 8 g/dL should be undertaken. Volume should be expanded to maintain a systolic blood pressure of 90 to 100 mm Hg and a heart rate of less than 100 beats per minute, but vigorous resuscitation with saline solution should generally be avoided because this may lead to recurrent variceal hemorrhage or accumulation of ascites and/or fluid at other anatomical sites. Use of recombinant factor VIIa therapy is not recommended in cirrhotic patients with GI hemorrhage at this time. Airway management is critical in patients with variceal hemorrhage, especially those with concomitant hepatic encephalopathy or severe bleeding. Elective or more emergent intubation may be required prior to diagnostic endoscopy. Combination pharmacological therapy plus endoscopic therapy with preferably EVL, or sclerotherapy if EVL is not technically feasible, is considered the most rational approach to the treatment of acute variceal bleeding.

Vasoactive drug therapy (usually octreotide) is routinely used early to stop or slow bleeding for patient management as soon as a diagnosis of variceal bleeding is suspected, and potentially even before EGD. Antibiotic therapy to prevent SBP and other infections, as well as to prevent rebleeding and decrease mortality, should be implemented. Figure 44–5 presents an algorithm for the management of variceal hemorrhage.

**Drug Therapy**

Drugs employed to manage acute variceal bleeding in the United States include (a) the somatostatin analogue octreotide and (b) vasopressin. These agents work as splanchnic vasoconstrictors, thus decreasing portal blood flow and pressure. Agents available
in other countries also include terlipressin, which is an analogue of vasopressin, and another somatostatin analogue, vapreotide.

**Somatostatin and Octreotide** Somatostatin is a naturally occurring tetradecapeptide hormone, and octreotide is a synthetic octapeptide that shares a four–amino acid segment with somatostatin and has similar pharmacologic activity with greater potency and longer duration of action as compared with somatostatin.43 Somatostatin and octreotide cause a reduction in portal pressure and port-collateral blood flow through inducing splanchnic vasoconstriction without causing the systemic effects associated with vasopressin.24,28 Octreotide is more available as both subcutaneous and intravenous injection, though the most recent recommended dosing of octreotide for variceal bleeding consists of an initial intravenous bolus of 50 mcg followed by a continuous intravenous infusion of 50 mcg per hour.28,37 Because octreotide is safe for continuation for multiple days and because around half of early recurrent bleeding occurs within the first 3 to 5 days, guidelines suggest continuation of octreotide for 5 days after acute variceal bleeding.28,37,40 Studies have been conducted comparing octreotide with placebo, with balloon tamponade, with vasopressin, and with glypressin for the treatment of acute variceal bleeding with somewhat mixed results.41-46 While studies comparing octreotide with placebo or with balloon tamponade did not find octreotide to be superior for controlling bleeding, octreotide was significantly better for survival as compared with balloon tamponade.41,42 No significant differences in bleeding control or mortality were found in studies comparing octreotide with vasopressin or terlipressin.43-46 A meta-analysis of studies of somatostatin analogues in general also failed to show a beneficial effect.47 A meta-analysis comparing either endoscopic therapy (with sclerotherapy or EVL) alone or endoscopic therapy plus octreotide, somatostatin, or vapreotide showed improved initial control of bleeding and 5-day hemostasis with combination therapy without any differences in mortality or severe adverse events.48 Octreotide used alone may be less effective for controlling bleeding due to tachyphylaxis and a more transient effect relative to terlipressin.49,50

Vasopressin (also known as antidiuretic hormone) is a potent, nonselective vasoconstrictor that reduces portal pressure by causing splanchnic vasoconstriction, which reduces splanchnic blood flow.24 Unfortunately, the vasoconstrictive effects of vasopressin are nonselective—the vasoconstriction is not restricted to the splanchnic vascular bed. Potent systemic vasooconstriction induces peripheral resistance, which reduces cardiac output, heart rate, and coronary blood flow. These effects on cardiac hemodynamics can lead to myocardial ischemia or infarction, arrhythmias, mesenteric ischemia, ischemia of the limbs, and cerebrovascular accidents. A meta-analysis of four randomized, controlled clinical trials of vasopressin for variceal hemorrhage demonstrated that vasopressin was significantly more effective than no treatment at controlling bleeding; however, mortality was not affected.24 Adverse effects were reported in one to two thirds of patients, and vasopressin was discontinued in about 25% of patients secondary to adverse effects. A meta-analysis comparing vasopressin and somatostatin in the management of acute esophageal variceal hemorrhage found somatostatin more efficacious for controlling acute hemorrhage from esophageal varices with significantly less adverse effects.51 Only four patients must be treated with somatostatin over vasopressin for one to derive additional benefit in terms of initial control of bleeding, and only nine patients need to be treated with somatostatin instead of vasopressin in order for one to experience benefit in terms of avoidance of rebleeding. Though somatostatin is not available in the United States today, its

![Figure 44-5. Management of acute variceal hemorrhage.](image-url)
The Baveno IV Consensus Report recommended that endoscopy be performed as soon as possible following admission in cases of suspected variceal hemorrhage, especially in cases of significant bleeding and in patients with suspected cirrhosis. Endoscopy is used to diagnose variceal bleeding, and endoscopic techniques, such as EVL and sclerotherapy, can be used in an attempt to stop variceal bleeding. EVL consists of placement of rubber bands around the varix through a clear plastic channel attached to the end of the endoscope. After the rubber bands are in place, the varix will slough off after 48 to 72 hours. Typically, the EVL procedure is repeated every 1 to 2 weeks until variceal obliteration is attained. Surveillance endoscopy is then performed 1 to 3 months after obliteration and then repeated every 6 to 12 months indefinitely. Endoscopic sclerotherapy involves injection of 1 to 4 mL of a sclerosing agent into the lumen of the varices to tamponade blood flow. EVL is more effective than sclerotherapy with greater control of hemorrhage, less risk for rebleeding, and lower likelihood of adverse events. No difference in mortality has been found between these two endoscopic procedures; however, HVPG is increased following both EVL and sclerotherapy, though HVPG decreases to baseline within 2 days following EVL and remains elevated for longer following sclerotherapy. Consensus recommendation calls for EVL (in conjunction with pharmacological therapy) as the recommended form of endoscopic therapy for acute variceal bleeding, though endoscopic sclerotherapy may be employed if ligation is technically difficult.

Endoscopic injection of the tissue adhesive N-butyl-cyanoacrylate to control acute gastric variceal bleeding as well as EVL was associated with a lower rate of rebleeding as compared with EVL in one trial. Endoscopic therapy with 2-octyl cyanoacrylate is effective for initial control of bleeding from fundal varices as well as prevention of rebleeding. Therefore, endoscopic therapy with these agents is recommended for patients with acute bleeding from gastric varices.

Interventional and Surgical Treatment Approaches

Standard therapy fails to control initial bleeding or early rebleeding in 10% to 20% of patients with acute variceal hemorrhage. In these cases, a salvage procedure, such as balloon tamponade or transjugular intrahepatic portosystemic shunt (TIPS), is necessary. Balloon tamponade is effective in controlling variceal bleeding temporarily; however, rebleeding is common after balloon deflation, and complications result in mortality rates of up to 20% with balloon tamponade. Sengstaken-Blakemore tubes are recommended for use in esophageal variceal bleeding. Linton tubes are preferred for bleeding from fundal gastric varices. Balloon tamponade should be reserved as a temporizing measure until a more definitive treatment, such as TIPS, can be performed.

In patients with acute variceal bleeding refractory to pharmacologic or endoscopic therapy, a decrease in portal pressure through use of the TIPS procedure is effective in controlling bleeding and preventing rebleeding. The TIPS procedure involves the placement of one or more stents between the hepatic vein and the portal vein (Fig. 44–6). TIPS (preferably with polytetrafluoroethylene-covered stents) is recommended for patients who fail to achieve hemostasis after a second attempt at endoscopic therapy. TIPS provides an effective decompressive shunt without laparotomy and can be employed regardless of Child-Pugh score, unlike shunt surgery, which is restricted to Child-Pugh class A patients. TIPS decreased the incidence of variceal rebleeding and decreased the incidence of deaths due to rebleeding. There was a significantly increased rate of posttreatment encephalopathy found in TIPS-treated patients.

Treatment Recommendations: Variceal Hemorrhage

Patients require cautious resuscitation with colloids and blood products to correct intravascular losses and to reverse existing coagulopathies. Drug therapy with octreotide should be initiated early to control bleeding and facilitate diagnostic and therapeutic endoscopy. Therapy is initiated with an intravenous bolus of 50 mcg and is followed by a continuous infusion of 50 mcg
per hour for 3 to 5 days. Monitor patients for hypo- or hyperglycemia, especially patients with diabetes, and assess for cardiac conduction abnormalities. Vasopressin is no longer recommended for control of variceal bleeding. Endoscopy is recommended in any patient with suspected upper gastrointestinal bleeding due to ruptured varices. EVL is the recommended form of endoscopic therapy, but endoscopic sclerotherapy may be employed if EVL is technically difficult. An additional endoscopic therapy option is injection of the tissue adhesive N-butyl-cyanoacrylate for gastric varices. Short-term antibiotic prophylaxis (maximum 7 days) is recommended. Appropriate choices include norfloxacin 400 mg twice daily or intravenous ciprofloxacin if the oral route is unavailable. In patients with advanced cirrhosis in areas of high quinolone resistance, intravenous ceftriaxone 1 g daily may be preferred. Surgical shunts and TIPS are employed as salvage therapy in patients who have failed repeated endoscopy and vasoactive drug therapy.

Secondary Prophylaxis: Prevention of Rebleeding Because rebleeding after initial control of variceal hemorrhage occurs in a median of 60% of patients within 1 to 2 years without treatment and because rebleeding carries a mortality rate of 33%, it is inappropriate to simply observe patients for evidence of further bleeding. Only patients who underwent shunt surgery or TIPS to control their initial acute bleeding require no further intervention as secondary prophylaxis. Patients who underwent one of these procedures to treat their initial bleed should be referred for transplant if they are a candidate. Candidates include those with a Child-Pugh score greater than or equal to 7 or MELD score greater than or equal to 15. Combination therapy with β-adrenergic blockers and chronic EVL to eradicate varices is the best treatment option for secondary prophylaxis of variceal bleeding. Secondary prophylaxis should be started as soon as possible following the acute bleed once the patient has had no bleeding for at least 24 hours and before the patient is discharged from the hospital. Alternatives for the secondary prevention of rebleeding include surgical or interventional shunting, but pharmacologic plus endoscopic interventions should be used as first-line therapy to prevent rebleeding.

Drug Therapy The combination of EVL and a nonselective β-adrenergic blocking agent provides the most rational approach for secondary prophylaxis because nonselective β-adrenergic blocking agents can protect against variceal rebleeding before variceal obliteration can be accomplished through EVL, and β-adrenergic blocking agents will also delay variceal recurrence. EVL plus nonselective β-adrenergic blocker has been compared with EVL alone for the prevention of rebleeding. Rebleeding rates were significantly lower in patients treated with combination therapy (23% and 14%) versus EVL alone (47% and 38%). A meta-analysis comparing combination endoscopic therapy (with either sclerotherapy or EVL) and nonselective β-adrenergic blocker versus either therapy alone found that combination therapy reduces overall and variceal rebleeding better than either therapy alone. The combination of EVL and nonselective β-adrenergic blocker should be employed in any patient who experiences first or recurrent variceal bleeding while on either EVL or nonselective β-adrenergic blocker alone.

The lowest rate of variceal rebleeding occurs in patients when pharmacologic therapy leads to a reduction in HVPG of greater than 20% of baseline or to a measurement less than 12 mm Hg. Ideally, portal pressure monitoring would help to assess the response to nonselective β-adrenergic blocker therapy and identify responders from nonresponders earlier in the treatment course. In order to utilize the HVPG measurement for clinical decision making, the technique used to make this measurement would first have to be standardized, including the best time to perform the repeat HVPG measurement.

Treatment Recommendations: Secondary Prophylaxis The combination of EVL plus pharmacologic therapy to prevent rebleeding is currently considered the most rational therapeutic approach. Pharmacologic therapy should be initiated with a nonselective β-blocker such as propranolol 20 mg twice daily or nadolol at a dose of 20 mg once daily. β-Blocker therapy can be titrated to achieve a goal heart rate of 55 to 60 beats per minute or the maximal tolerated dose. Monitor patients for evidence of heart failure, bronchospasm, and glucose intolerance, particularly hypoglycemia in patients with insulin-dependent diabetes. EVL should be conducted every 1 to 2 weeks until variceal obliteration, and then the patient should be followed by surveillance endoscopy in 1 to 3 months and then every 6 to 12 months. Combination therapy with nonselective β-blocker plus isosorbide mononitrate can be considered in patients who are unable to undergo EVL. Patients who cannot tolerate or who fail pharmacologic and endoscopic interventions can be considered for TIPS or surgical shunting to prevent bleeding. A summary of evidence-based treatment recommendations regarding portal hypertension and variceal bleeding is found in Table 44–3.

Ascites and Spontaneous Bacterial Peritonitis Patients with cirrhosis experience overt fluid retention and ascites as liver disease progresses. The classic physical exam findings of ascites are a bulging abdomen with shifting flank dullness. The development of ascites in patients with cirrhosis is an indication of advanced liver disease and is a poor prognostic sign. The principle therapeutic goals for patients with ascites are to control the ascites; to prevent or relieve ascites-related symptoms such as dyspnea, abdominal pain, and abdominal distention; and to prevent life-threatening complications such as SBP and the hepatorenal syndrome. Treatment of ascites is expected to have little effect on survival, however. Workup includes a history and physical exam, abdominal paracentesis and/or ultrasound,

Recommendation grading:
Class I—Conditions for which there is evidence and/or general agreement
Class IIa—Conditions for which there is conflicting evidence and/or a divergence of opinion
Class IIb—Efficacy less well established
Class III—Conditions for which there is evidence and/or general agreement that treatment is not effective and/or potentially harmful

Level A—Data from multiple randomized trials or meta-analyses
Level B—Data derived from single randomized trial or nonrandomized studies
Level C—Only consensus opinion, case studies, or standard of care

Data from reference 28.

Management of Ascites and Spontaneous Bacterial Peritonitis

The following treatment guidelines for the management of adult patients with ascites was determined by physical exam or radiographic studies, abdominal paracentesis should be performed, and ascitic fluid analysis should include a cell count with differential, ascitic fluid total protein, and a serum-ascites albumin gradient (SAAG). If infection is suspected, ascitic fluid cultures should be obtained at the time of the paracentesis. The SAAG can accurately determine whether ascites is a result of portal hypertension or another process. If the SAAG is greater than 1.1 g/dL, the patient almost certainly has portal hypertension and will usually be responsive to salt restriction and diuretics. If the SAAG is less than 1.1 g/dL, the patient likely does not have portal hypertension and, except in cases of nephrotic syndrome, is less likely to respond to salt restriction and diuretics. The treatment of ascites secondary to portal hypertension is relatively straightforward and includes abstinence from alcohol, sodium restriction, and diuretics.

1 Abstinence from alcohol is an essential element of the overall treatment strategy. Abstinence from alcohol can result in improvement of the reversible component of alcoholic liver disease, resolution of ascites, or improved responsiveness of ascites to medical therapy. Patients with cirrhosis not caused by alcohol have less reversible liver disease, and, by the time ascites is present, these patients may be best managed with liver transplantation rather than protracted medical therapy.

Beyond avoidance of alcohol, the primary treatment of ascites due to portal hypertension and cirrhosis is salt restriction and oral diuretic therapy. Fluid loss and weight change depend directly on sodium balance in these patients. Evaluation of urinary sodium excretion, preferably utilizing a 24-hour urine collection, may be helpful when rapidity of weight loss is less than desired. Severe hyponatremia, defined as serum sodium less than a threshold of 120 to 125 mEq/L, does warrant fluid restriction. However, rapid correction of asymptomatic hyponatremia is not recommended as patients with cirrhosis are usually asymptomatic until their serum sodium concentrations are less than 110 mEq/L or unless the decline in serum sodium is rapid.

Diuretic Therapy

The AASLD practice guidelines recommend that diuretic therapy be initiated with the combination of spironolactone and furosemide. At one time, spironolactone was commonly recommended for initial therapy as a single agent. However, due to the likelihood for development of drug-induced hyperkalemia with spironolactone when used as monotherapy, the drug is now recommended only for use as a lone diuretic agent in patients with minimal fluid overload. If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. In patients with refractory ascites, serial paracenteses may be employed. Albumin infusion postparacentesis is controversial, but reasonable for extraction volumes exceeding 5 liters. Laboratory tests for renal function and electrolytes need to be monitored during therapy. Referral for liver transplantation should be made in patients with refractory ascites. TIPS is a therapeutic modality for the treatment of refractory ascites that may be considered in appropriately selected patients. Peritoneovenous shunting may be considered in treatment refractory patients who are not candidates for paracenteses, transplant, or TIPS.

and ascitic fluid analysis. The treatment of ascites is based on oral diuretics and is carried out in a slow, stepwise fashion. Treatment of ascites should be initiated only in stable patients (e.g., those without ongoing variceal hemorrhage, bacterial infection, or renal dysfunction).

SBP is an infection of ascitic fluid that occurs in the absence of any evidence of an intra-abdominal, surgically treatable source of infection. SBP is a common complication that develops in 10% to 20% of patients hospitalized with severe liver disease, cirrhosis, and ascites. The key mechanism behind the development of SBP is thought to be bacterial translocation. Decreased motility of the gastrointestinal tract with disturbances of the gut flora, changes in the structure of the gastrointestinal tract, and reduced local and humoral immunity combine to lead to the free flow of microorganisms and endotoxins to the mesenteric lymph nodes. Most episodes of SBP are caused by Escherichia coli, Klebsiella pneumonia, and pneumococci. Symptoms and signs of SBP include fever, abdominal pain, abdominal tenderness, rebound, encephalopathy, renal failure, acidosis, peripheral leukocytosis, and altered mental status. Paralytic ileus, hypotension, and hypothermia are poor prognostic indicators. Thirteen percent of patients with SBP present with no symptoms. For this reason, a diagnostic paracentesis with analysis of ascitic fluid should be performed in all patients admitted with ascites. Spontaneous bacterial peritonitis is diagnosed when there is possible ascitic fluid bacterial culture and ascitic fluid cell counts show an absolute polymorphonuclear (PMN) leukocyte count of greater than or equal to 250 cells/mm³.

The AASLD practice guidelines recommend that diuretic therapy be initiated with the combination of spironolactone and furosemide. At one time, spironolactone was commonly recommended for initial therapy as a single agent. However, due to the likelihood for development of drug-induced hyperkalemia with spironolactone when used as monotherapy, the drug is now recommended only for use as a lone diuretic agent in patients with minimal fluid overload. If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. In patients with refractory ascites, serial paracenteses may be employed. Albumin infusion postparacentesis is controversial, but reasonable for extraction volumes exceeding 5 liters. Laboratory tests for renal function and electrolytes need to be monitored during therapy. Referral for liver transplantation should be made in patients with refractory ascites. TIPS is a therapeutic modality for the treatment of refractory ascites that may be considered in appropriately selected patients. Peritoneovenous shunting may be considered in treatment refractory patients who are not candidates for paracenteses, transplant, or TIPS.
**Spontaneous Bacterial Peritonitis**

Relatively broad-spectrum antibiotic therapy that adequately covers the three most commonly encountered pathogens (Escherichia coli, Klebsiella pneumoniae, and pneumococci) is warranted in patients with documented or suspected SBP. Empirical therapy should not be delayed while awaiting culture results. In some patients, signs and symptoms of infection are present such as fever, abdominal pain, and unexplained encephalopathy at the bacterascites stage (i.e., signs and symptoms are present before the PMN count in the ascitic fluid is elevated). In these patients, signs and symptoms of infection justify empiric antibiotic therapy until culture results are known, regardless of the PMN count in the ascitic fluid.

Cefotaxime 2 g every 8 hours, or a similar third-generation cephalosporin, is considered the drug of choice for SBP. Cefotaxime is more effective than the combination of ampicillin and tobramycin. A 5-day course of antibiotic therapy was as efficacious as 10 days of therapy in a randomized trial involving 100 patients with SBP. Ofloxacin 400 mg every 12 hours administered orally for an average of 8 days is equivalent to intravenous cefotaxime for treatment of SBP in patients without vomiting, shock, significant hepatic encephalopathy, or serum creatinine over 3 mg/dL. Intravenous ciprofloxacin offers another potential treatment alternative. Patients with SBP who previously received quinolone therapy as prophylaxis should be treated with an alternative agent since patients who have received quinolone therapy may become infected with quinolone-resistant flora.

Secondary bacterial peritonitis, ascitic fluid infection caused by a surgically treatable intraabdominal source, can masquerade as SBP. Free perforation should be considered when multiple or atypical organisms are cultured, a very high ascitic fluid PMN count is seen, or when at least two of the following are seen on ascitic fluid analysis: total protein greater than 1 g/dL, lactate dehydrogenase greater than the upper limit of normal for serum, and glucose less than 50 mg/dL. A 48-hour follow-up PMN count that rises above pretreatment levels despite antibiotic treatment is indicative of secondary nonperforation peritonitis. Patients with free perforation or nonperforation secondary peritonitis should receive a third-generation cephalosporin plus anaerobic coverage in addition to undergoing laparotomy.

**Treatment Recommendations: Ascites and Spontaneous Bacterial Peritonitis**

Adult patients admitted to the hospital with new-onset ascites should have an abdominal paracentesis performed to establish the SAAG, the ascitic fluid cell count and differential, and the ascitic fluid total protein. If ascitic fluid infection is suspected, ascitic fluid should be cultured at the bedside.

Patients who drink alcohol should be strongly discouraged from further alcohol use. Sodium restriction to 2,000 mg/day, together with spironolactone and furosemide, is the mainstay of therapy. Diuretic therapy should be initiated with single morning doses of spironolactone 100 mg and furosemide 40 mg administered orally. Titrate diuretic therapy every 3 to 5 days using the 100 mg:40 mg ratio to attain adequate natriuresis and weight loss (reasonable daily weight loss goal is 0.5 kg). Maximum daily doses are 400 mg spironolactone and 160 mg furosemide. Combination ratio is used because it usually maintains normokalemia. Fluid restriction, unless the serum sodium is less than 120 to 125 mEq/L, and bed rest are not recommended. Monitor urinary sodium excretion using a 24-hour urine collection and monitor serum potassium and renal function frequently. Avoid rapid correction of asymptomatic hyponatremia in patients with cirrhosis. If tense ascites is present, paracentesis should be performed prior to institution of diuretic therapy and salt restriction. For patients who respond to diuretic therapy, this approach is preferred over the use of serial paracenteses. Discontinue diuretic therapy in patients who experience uncontrolled or recurrent encephalopathy, severe hyponatremia (serum sodium less than 120 mEq/L) despite fluid restriction, or renal insufficiency (serum creatinine greater than 2 mg/dL). Serial paracenteses may be considered for patients with refractory ascites and albumin infusion of 6 to 8 g/L of fluid removed can be considered postparacentesis when paracentesis volumes exceed 5 L.

Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm³ should receive empiric antibiotic therapy with intravenous cefotaxime 2 g every 8 hours or a similar third-generation cephalosporin. Oral ofloxacin 400 mg twice daily may be an alternative option in patients without prior exposure to quinolones, vomiting, shock, severe encephalopathy, or serum creatinine over 3 mg/dL. Patients with ascitic fluid PMN counts less than 250 cells/mm³ but with signs and symptoms of infection (symptoms such as abdominal pain, abdominal tenderness, and fever) should also receive empiric antibiotic treatment. Patients with ascitic fluid PMN counts greater than or equal to 250 cells/mm³ and suspicion of SBP should also receive 1.5 g of albumin per kilogram body weight within 6 hours of detection and 1 g per kilogram body weight on day 3 if they also have a serum creatinine over 1 mg/dL, blood urea nitrogen over 30 mg/dL, or total bilirubin over 4 mg/dL.

All patients who have survived an episode of SBP should receive long-term antibiotic prophylaxis with daily norfloxacin 400 mg or double strength trimethoprim-sulfamethoxazole. Long-term prophylaxis should also be considered for the prevention of SBP in patients with low-protein ascites (less than 1.5 g/dL) who also have one of the following: serum creatinine greater than or equal to 1.2 mg/dL, blood urea nitrogen greater than or equal to 25 mg/dL, serum sodium less than or equal to 130 mEq/L, or Child-Pugh score of greater than or equal to 9 with bilirubin greater than or equal to 3 mg/dL. Short-term prophylaxis (7 days) is indicated in patients with cirrhosis and gastrointestinal hemorrhage. A summary of evidence-based treatment recommendations regarding ascites and SBP is found in Table 44–4.

**HEPATIC ENCEPHALOPATHY**

The clinical manifestations of HE vary widely. Patients with minimal HE do not suffer from clinically overt cognitive dysfunction; nevertheless, it adversely affects their ability to function socially and perform in the workplace, and it may also affect their ability to drive safely. Episode HE refers to precipitated, spontaneous, or recurrent acute episodes of HE. Recurrent HE refers to two spontaneous or precipitated episodes of HE that occur within 1 year. Persistent HE refers to mild, severe, or treatment-dependent symptoms that are chronic in nature and negatively impact a patient’s quality of life.

The prevalence of HE among cirrhotics is variable but may be found in up to 70% of patients. To determine the severity of HE, a grading system that relates neurologic and neuromuscular signs can be used (Table 44–5). Presently, the primary substances thought to be involved in the development of HE are ammonia, glutamate, manganese, and the γ-aminobutyric acid (GABA)-benzodiazepine receptor agonists.

**Management of Hepatic Encephalopathy**

Episodic HE may develop in a clinically stable cirrhotic patient as the result of a precipitating event. Table 44–6 lists the most commonly encountered precipitating factors and suggests general treatment alternatives. Table 44–7 describes the treatment goals for patients with HE and contrasts the differences between episodic

**Recommendation grading:**
- Class I—Conditions for which there is evidence and/or general agreement
- Class II—Conditions for which there is conflicting evidence and/or a divergence of opinion
- Class IIa—Weight of evidence/opinion is in favor of efficacy
- Class IIb—Efficacy less well established
- Class III—Conditions for which there is evidence and/or general agreement that treatment is not effective and/or potentially harmful
- Level A—Data from multiple randomized trials or meta-analyses
- Level B—Data derived from single randomized trial or nonrandomized studies
- Level C—Only consensus opinion, case studies, or standard of care

Ammonia generated by Helicobacter pylori in the stomach may be associated with precipitating or worsening HE in patients with cirrhosis. However, a prospective clinical trial showed no significant improvement in mental status or serum ammonia levels in patients with HE who underwent H. pylori eradication. Therefore, routine eradication of H. pylori is not recommended.

Rifaximin is a synthetic antibiotic structurally similar to rifampicin with a systemic absorption of only 0.4%. Rifaximin lowers blood ammonia levels and improves neuropsychiatric symptoms in HE. Rifaximin 1,200 mg/day has been compared with lactitol 60 g/day in patients with grade I to III HE for 5 to 10 days. Comparable percentages of patients showed clinical improvement at the end of the treatment period; however, improvements in blood ammonia concentrations and in the HE index were significantly greater among rifaximin-treated patients. There was also a higher number of patients who showed complete resolution of their neuropsychiatric symptoms with rifaximin treatment versus the nonabsorbable disaccharide lactitol. Rifaximin has also been compared with neomycin in patients with grade I to III HE. In this randomized, double-blind comparison, patients were treated for 21 days with either rifaximin 1,200 mg daily or neomycin 3 g/day. While significant improvements were seen in both groups, improvements in psychometric performance and blood ammonia concentrations were significantly greater in patients treated with rifaximin. Also, while no adverse events were reported in the rifaximin-treatment group, nearly a fourth of neomycin-treated patients experienced increases in blood urea nitrogen and serum creatinine levels, and nearly a third reported nausea, abdominal pain, and vomiting.

the time period available for ammonia absorption, (b) through leaching of ammonia from the circulation into the colon and increasing bacterial uptake of ammonia by colonic bacteria, and (c) through reducing ammonia production by the small intestine by interfering directly with the uptake of glutamine by the intestinal wall and its subsequent metabolism to ammonia. Upon evaluation of the numerous clinical trials studying the effectiveness of lactulose in the treatment of HE, one may determine that the standards of evidence-based medicine have not been met. In fact, lactulose plus neomycin was not better than placebo for the management of acute HE. Despite this and because reevaluation of lactulose for the management of HE (especially acute HE) would require a new clinical trial, bowel cleansing through lactulose administration remains a cornerstone in HE therapy. Inhibiting the activity of urease-producing bacteria by using neomycin or metronidazole can decrease production of ammonia. Neomycin at doses of 3 to 6 g daily can be given for 1 to 2 weeks during an acute episode of HE. For persistent HE, a dose of 1 to 2 g daily could be used with periodic renal and annual auditory monitoring. Despite poor absorption, chronic use of neomycin can lead to irreversible ototoxicity, nephrotoxicity, and the possibility of staphylococcal superinfection. As such, neomycin should not be considered first-line therapy for HE. In patients with an inadequate response to lactulose alone, combination therapy with neomycin may be tried. Metronidazole initiated at 250 mg twice daily may also produce a favorable clinical response in HE. However, neurotoxicity caused by impaired hepatic clearance of the drug may be problematic.

Ammonia removal can be enhanced by stimulating its detoxification. This is done by supporting alternative metabolic pathways, which can reduce blood ammonia concentrations. l-Ornithine l-aspartate stimulates residual hepatic urea cycle activity and promotes peripheral glutamine synthesis. Intravenous l-Ornithine l-aspartate is effective in cirrhotic patients with grade 1 and grade 2 HE to reduce blood ammonia and improve clinical symptoms of...

Drugs Affecting Neurotransmission

The GABA-receptor complex is the primary inhibitory neural network within the central nervous system. An enhanced GABA-ergic tone and an increased amount of endogenous benzodiazepines may contribute to HE.97 Based on evidence of an increase in benzodiazepine receptor ligands in patients with hepatic encephalopathy, flumazenil has been evaluated for the treatment of HE.98 Among five prospective, placebo-controlled trials, three reported benefit with flumazenil, whereas two found no difference when compared to placebo. With dosages of 0.2 to 15 mg IV, response rates were variable, ranging from 17% to 78%. Improvements, however, were often transient. Flumazenil 1 mg intravenous bolus may be considered for short-term therapy in refractory patients with suspected benzodiazepine intake, but cannot be recommended for routine clinical use.14

Alterations of dopaminergic neurotransmission have also been thought to play a role in the symptoms of HE, particularly the extrapyramidal signs.14 Improvements of extrapyramidal symptoms have been reported with bromocriptine therapy.79 Bromocriptine 30 mg twice daily is indicated for chronic HE treatment in patients who are unresponsive to other therapies.14 Prolactin levels may become elevated during bromocriptine treatment, and oototoxicity is possible.82 Bromocriptine should be avoided in patients with ascites.82

Treatment Recommendations: Hepatic Encephalopathy

Treatment recommendations depend on the type of HE being managed: episodic HE, persistent HE, or minimal HE.87 The general approach to the management of HE is first to identify patients with acute episodic HE and then to provide aggressive management of any precipitating events (see Table 44–7).89 When the precipitating event has been discovered and appropriate therapy initiated, then steps to rapidly reverse the encephalopathy should be implemented.7 The mainstay of therapy of HE involves measures to lower blood ammonia concentrations and includes diet therapy, lactulose, and antibiotics alone or in combination with lactulose. Other commonly used adjunctive therapies include zinc replacement in patients with zinc deficiency, flumazenil, and possibly bromocriptine.

In patients with episodic HE, protein is withheld or limited while maintaining the total caloric intake until the clinical situation improves. Then dietary protein is titrated back up based on tolerance, increasing gradually to a total of 1 to 1.5 g/kg per day. Consider the substitution of meat-source protein with vegetable or dairy protein. Zinc sulfate supplementation at a dose of 220 mg twice daily is recommended for long-term management in patients with cirrhosis who are zinc deficient.

In episodic HE, lactulose is initiated at a dose of 45 mL orally every hour (or by retention enema: 300 mL lactulose syrup in 1 L water held for 60 minutes) until catharsis begins. The dose is then decreased to 15 to 45 mL orally every 8 to 12 hours and titrated to produce two to three soft stools per day. The enema is retained for 1 hour with the patient in the Trendelenburg position. For chronic encephalopathy, dosing is the same except that the initial hourly administration is not required. Patients are maintained on this regimen to prevent recurrence of episodic HE. Monitor electrolytes periodically, follow patients for changes in mental status, and titrate to the number of stools as already described.

Antibiotic therapy with either metronidazole (initiated at 250 mg twice daily but titrated up to four times daily in the literature) or neomycin (dose at 3 to 6 g/day for 1 to 2 weeks for episodic HE and 1 to 2 g/day for persistent HE) are reserved for patients who have not responded to diet and lactulose therapy and when the combination may provide additive effects and improved clinical response. Because rifaximin 400 mg three times daily provides similar effectiveness and has less risk of side effects as compared with other antibiotic options, rifaximin is often used today as second-line therapy for patients who have inadequate response to lactulose or are unable to tolerate or adhere to therapy with lactulose.57

**SYSTEMIC COMPLICATIONS**

In addition to the more common complications of chronic liver disease discussed earlier, other complications can occur, including hepatorenal syndrome, hepatopulmonary syndrome, coagulation disorders, and endocrine dysfunction.

Hepatorenal syndrome, which is a functional renal failure in the setting of cirrhosis, occurs in the absence of structural kidney damage.100 It develops in patients with cirrhosis as a result of intense renal vasoconstriction, which results from extreme systemic vasodilatation. The resultant reduction in blood supply to the kidneys causes avid sodium retention and oliguria. As liver disease progresses, systemic vasodilatation worsens and, subsequently, increased renal vasoconstriction occurs and renal blood flow is further decreased. As this occurs, the heart’s response becomes insufficient to maintain perfusion pressure, which the kidneys rely heavily upon at this point to maintain adequate blood flow. Hepatorenal syndrome is common and develops in approximately 20% of hospitalized patients with cirrhosis.

Management of hepatorenal syndrome begins with a first step of discontinuing diuretics and any other medication that could potentially decrease effective blood volume and to expand the intravascular volume with intravenous albumin at a dose of 1 g/kg up to a maximum of 100 g.77 Precipitating factors such as infection, fluid loss, and blood loss should be investigated and treated if found. Liver transplantation is the only definitive therapy for hepatorenal syndrome and the only therapy that will prolong survival. Therapies used to bridge patients until transplantation include arteriolar vasoconstrictor based treatments with terlipressin or midodrine plus octreotide used in addition to intravenous albumin infusion as already discussed.

Hepatopulmonary syndrome affects somewhere between 5% and 32% of patients with cirrhosis.80 This abnormality is characterized by a defect in arterial oxygenation, which is caused by the pulmonary vascular dilatation that occurs in the presence of liver disease. Less commonly, pleural and pulmonary arteriovenous shunting can occur as well as portopulmonary venous anastomoses. These patients present with dyspnea on exertion, at rest, or both. Cirrhotic patients with these findings should be evaluated for hepatopulmonary syndrome, which is diagnosed based upon the presence of arterial hypoxemia. Arterial hypoxemia is defined based on measurements of the partial pressure of oxygen that are performed with patients sitting and at rest. Testing for an increased alveolar–arterial oxygen gradient is also particularly important as this gradient can rise abnormally before the patient’s partial pressure of oxygen measurement becomes abnormally low. Long-term management requires supportive therapy with supplemental
Cirrhosis modulates the behavior of drugs in the body by inducing metabolic processes: phase I reactions and phase II reactions. Phase I reactions involve the cytochrome P450 system and include hydrolysis, oxidation, dealkylation, and reduction reactions. Phase II reactions involve conjugation of the drug with an endogenous molecule such as sulfate or an amino acid, rendering it more water soluble and enhancing its elimination. Drugs metabolized by phase I reactions, especially oxidation, tend to be significantly impaired in patients with cirrhosis, whereas drugs eliminated by conjugation are relatively unaffected.

The variability and complexity of the interaction between the extent and severity of liver disease and individual characteristics of the drug make it difficult to predict the degree of pharmacokinetic perturbation in an individual patient. Unfortunately, there are no sensitive and specific clinical or biochemical markers that allow us to quantify the extent of liver insufficiency or the degree of metabolic activity. In addition, renal insufficiency and alterations that commonly accompany cirrhosis further complicate empiric dosing recommendations in these patients. Dosing recommendations are most commonly nonspecific, with recommendations labeled for patients with mild to moderate liver impairment. Dosing information for patients with more severe liver impairment is not available. As a result, when patients with cirrhosis require therapy with drugs that undergo hepatic metabolism (e.g., benzodiazepines), monitoring response to therapy and anticipating drug accumulation and enhanced effects is essential. In the case of benzodiazepines, selection of an agent such as lorazepam, an intermediate-acting agent that is metabolized via conjugation and has no active metabolites, is easier to monitor than a drug such as diazepam, a long-acting benzodiazepine that is oxidized in the liver and has an active metabolite with a long half-life of its own.

The complications seen in patients with chronic liver disease are essentially functional as a secondary effect of the circulatory and metabolic changes that accompany liver failure. Consequently, liver transplantation is the only treatment that can offer a cure for complications of end-stage cirrhosis.

**PHARMACOKINETIC AND PHARMACODYNAMIC CHANGES IN LIVER FAILURE**

Cirrhosis modulates the behavior of drugs in the body by inducing kinetic alterations in drug absorption, distribution, and clearance. Additionally, patients with cirrhosis may exhibit pharmacodynamic changes with increased sensitivity to the effects of certain drugs, namely opiates, benzodiazepines, and nonsteroidal antiinflammatory drugs (NSAIDs). These pharmacodynamic changes are separate and distinct from the enhancement of drug effects seen in cirrhosis patients as a result of pharmacokinetic changes. Hepatic drug clearance is primarily dependent upon protein binding, hepatic blood flow, and metabolic enzyme activity. The pathophysiologic changes that occur in patients with cirrhosis, including reduced liver blood flow, intra- and extrahepatic portal-systemic shunting, diminished metabolic and synthetic function, and capillarization of the sinusoids, can have a significant impact on each of these factors. The consequence of these changes is a reduction in intrinsic metabolic activity, a reduction in the delivery of blood to the liver that decreases clearance and prolongs half-life, and a reduction in the degree of protein binding that increases the fraction of unbound drug in the serum. Finally, patients with cirrhosis frequently accumulate large amounts of interstitial fluid resulting in substantial changes in the volume of distribution, which also prolongs drug half-life. These changes occur most commonly in combination in patients with cirrhosis and are dynamic throughout the disease course. The effect that these changes will have depends on the drug and the type of biotransformation that the drug undergoes.

Drugs with a high extraction ratio (high-extraction drugs) are dependent on blood flow for metabolism, and the rate of metabolism will be sensitive to changes in blood flow. Drugs with a low extraction ratio (low-extraction drugs) are dependent on intrinsic metabolic activity for metabolism, and the rate of metabolism will reflect changes in intrinsic clearance and protein binding. Furthermore, hepatic biotransformation involves two types of metabolic processes: phase I reactions and phase II reactions. Phase I reactions involve the cytochrome P450 system and include hydrolysis, oxidation, dealkylation, and reduction reactions. Phase II reactions involve conjugation of the drug with an endogenous molecule such as sulfate or an amino acid, rendering it more water soluble and enhancing its elimination. Drugs metabolized by phase I reactions, especially oxidation, tend to be significantly impaired in patients with cirrhosis, whereas drugs eliminated by conjugation are relatively unaffected.

**PHARMACOECONOMIC CONSIDERATIONS**

Two studies, both related to the prevention of variceal bleeding and published recently, are mentioned here. A recent analysis provides evidence that HVPG monitoring is not cost-effective for use in patients with varices and no history of variceal bleeding as compared to treatment with standard β-blocker therapy without invasive monitoring. A cost-utility evaluation of secondary prophylaxis therapies concluded that patients are best served by treatment with either endoscopic band ligation or endoscopic band ligation plus medical management as compared with TIPS placement. Because treatment approaches for patients with cirrhosis can range from supportive medical therapy to repeated endoscopic procedures with serious complications to liver transplantation, the need for application of economic analysis is obvious. Of critical importance is the question of when, in the course of chronic liver disease, the various treatment interventions are employed and whether liver transplantation should be attempted earlier, thereby avoiding most of the complications associated with chronic liver disease.

**EVALUATION OF THERAPEUTIC OUTCOMES**

Table 44–8 summarizes the management approach for patients with cirrhosis, including monitoring parameters and therapeutic outcomes. Cirrhosis is generally a chronic progressive disease that requires aggressive medical management to prevent or delay common complications. Table 44–8 also lists monitoring criteria that need to be carefully followed in order to achieve the maximum benefit from the medical therapies employed and prevent adverse effects. A therapeutic plan including therapeutic end points for each medical and diet therapy needs to be developed and discussed with the patient.

Drug-Induced Liver Disease

WILLIAM R. KIRCHAIN AND RONDALL E. ALLEN

KEY CONCEPTS

1. The liver itself through its normally functioning enzymes and processes often causes a drug to become toxic through a process known as bioactivation.

2. Drug-induced liver disease occurs as several different clinical presentations: idiosyncratic reactions, allergic hepatitis, toxic hepatitis, chronic active toxic hepatitis, toxic cirrhosis, and liver vascular disorders.

3. The mechanisms of drug-induced liver disease are diverse, representing many phases of biotransformation, and are susceptible to genetic polymorphism.

4. A fulminant or severe drug-induced reaction within the liver usually involves the immune system and is marked by large scale cell necrosis.

5. The assessment of a possible liver injury caused by drugs should include what is known in the literature, the timing involved, the clinical course, and, always, an exploration for preexisting conditions that may have encouraged the lesion’s development.

6. Liver enzyme assays can help to determine if a particular type of liver damage is present.

7. Monitoring for drug-induced liver disease must be tailored to the drug and the patient’s potential risk factors.

The number of drugs associated with adverse reactions involving the liver is extensive. One of the more common reasons for the withdrawal of a drug from the marketplace is an elevation of serum concentrations of liver enzymes. Its impact on the pharmaceutical industry has led regulatory agencies to withdraw drugs from the market, restrict the use of certain medications, and issue black box warnings.

Alcohol-induced liver disease is the most common type of drug-induced liver disease. All other drugs together account for less than 10% of patients hospitalized for elevated liver enzymes. Drug-induced liver disease accounts for as much as 20% of acute liver failure in pediatric populations and at least that many of adults with acute liver failure. In approximately 75% of these cases liver transplantation is ultimately required for patient survival. Of patients who required liver transplantation according to the United Network for Organ Sharing, acetaminophen, isoniazid, antiepileptics, and antibiotics collectively account for just over 60% of cases. In a prospective analysis of 1,200 patients admitted to a hospital in South Carolina for liver dysfunction, isoniazid accounted for 21 of 132 cases with various antibiotics and sulfa drugs accounting for another 30 cases. Overall, the reported incidence of drug-induced liver disease is around 1 in 10,000 to 1 in 100,000 patients.

The liver’s function affects almost every other organ system in the body, but there are no specific diagnostic tests for drug-induced liver disease or a means to single out an implicated drug. Therefore it is important to know the patterns of drug-related pathology in order to assess adverse reactions when they occur. The liver’s normal metabolic outcome is to decrease the reactivity of a drug or toxin, in effect deactivating it. In many of the patterns of damage that this chapter will review, the first step is a net increase in reactivity that results from the normal processes of metabolism in the liver. This now bioactivated compound if left unconjugated or otherwise unbound is free to react in uncontrolled ways within the cell.

PATTERNS OF DRUG-INDUCED LIVER DISEASE

HEPATOCELLULAR INJURY

Hepatocellular injury is characterized by significant elevations in the serum aminotransferases which usually precede elevations in total bilirubin levels and alkaline phosphatase levels. Most injuries occur within 1 year of initiating the offending agent. Hepatocellular injury can lead to fulminant hepatitis with a corresponding 20% survival rate with supportive care. For those patients who present with the combination of hepatocellular injury and jaundice, there is a 10% mortality rate. Acarbose, allopurinol, fluoxetine, and losartan are capable of causing hepatocellular injury.

Hepatocellular injuries can be further subdivided by specific histologic patterns and clinical presentations. Centrolobular necrosis, steatohapatitis (steatonecrosis), phospholipidosis, and generalized hepatocellular necrosis are each identifiable by particular biopsy results and subtle differences in clinical presentation.

CENTROLOBULAR NECROSIS

Centrolobular necrosis is often a dose-related, predictable reaction; however, it also can be associated with idiosyncratic reactions. Also called direct or metabolite-related hepatotoxicity, centrolobular necrosis is usually the result of the production of a toxic metabolite (Fig. 45–1). The damage spreads outward from the middle of a lobe of the liver.
Gastrointestinal Disorders

SECTION 4

Drug

Presents to the liver (dependent on hepatic blood flow, percent protein binding, etc)\(^1\)\(^2\)

Uptake into hepatocyte\(^3\)

Drug

Depending on the individual agent involved, the drug either remains in the cytoplasm, migrates into the mitochondria, or is transported into the nucleus of the hepatocyte.

Metabolized by either cytochrome P450 superfamily or by one or more other enzyme families.\(^4\)

Reactive metabolite

Also known as a “free radical” depending on its inherent reductive-oxidative potential.\(^5\)

Depending on where in the cell the drug migrated or was transported.

Reactive metabolite

In the mitochondrial endoplasmic reticulum

Indiscriminate, unregulated reactions lead to acceleration of cellular stress

Overtakes apoptosis\(^8\)

Necrocytolysis\(^9\)

Induces innate immune response\(^10\)

Hepatitis

Reactive metabolite

In the cytoplasm endoplasmic reticulum

Indiscriminate, unregulated reactions to circulating enzymes and structural proteins

Acceleration of cellular stress

Formation of haptens

Induces innate immune response

Allergic hepatitis

Reactive metabolite\(^11\)

Uptake into hepatocyte\(^3\)

When no conjugating enzyme has a high enough affinity or more commonly when proteins like Glutathione are depleted.\(^5\)\(^7\)

Under the influence of conjugating enzymes to a protein such as the glutathione, the production of which is genetically mediated.\(^5\)\(^6\)

Conjugated then excreted

FIGURE 45-1. A general diagram of biotransformation. (1) Hepatic blood flow, which changes proportionately with changes in cardiac output, delivers the drug to the liver. (2) Protein binding is most affected by nutritional status and competing drugs. (3) The drug is actively transported into the hepatocyte by the organic anion transport pump, a transmembrane protein. (4) The metabolite (drug) interacts with one of a number of enzymes, the most common being CYP2C9, 2C19, 2D6, and 3A4. This family of enzymes is regulated by the complementary DNA xenobiotic receptor. The xenobiotic receptor is in turn upregulated by other drugs, changes in cholesterol catabolism, and bile acids. The immediate result of the action of these phase I enzymes is the production of a reactive metabolite. (5) The unstable metabolite then reacts with glucuronidase, various transferases, or hydroxylases to form a conjugated metabolite. The efficacy of these enzymes is affected by the patient’s nutritional state and genetic polymorphism, leading to variations in individual risk for toxicity. (6) The conjugated metabolite is removed from the hepatocyte by the canalicular membrane export pump, one of a large family of membrane proteins (other members of this family pump conjugated metabolites back into the blood for excretion by the kidney). These proteins are subject to genetic polymorphism as well, again leading to some patients having an increased risk for toxicity. (7) If unable to form a conjugate, the unstable metabolite can participate in oxidative reactions that damage lipids, proteins, or even DNA. (8) The normal process of cellular aging, death, and reabsorption by surrounding cells. (9) Widespread, rapid cellular death with the creation of multiple antigens. (10) Activation Kupffer cells, killer cells, B-cells, and other T-cells with the associated production of inflammatory cytokines the relative numbers of which and the innate activity of each mediated by genetic polymorphism. (11) Drugs or active metabolites that are transported or diffuse into the mitochondria or the nucleus can damage DNA, leading to mutagenicity and ultimately hepatic cancers.
Patients suffering from centrolobular necrosis tend to present in one of two ways, depending on the extent of necrosis. Mild drug reactions, involving only small amounts of parenchymal liver tissue, may be detected as asymptomatic elevations in the serum aminotransferases. If the reaction is diagnosed at this stage, most of these patients will recover with minimal cirrhosis and thus minimal chronic liver impairment. More severe forms of centrolobular necrosis are accompanied by nausea, vomiting, upper abdominal pain, and jaundice.\(^\text{1,12}\)

These reactions are predictable, often dose-related effects in the liver caused by specific agents. When taken in overdose, acetaminophen becomes bioactivated to a toxic intermediate known as N-acetyl-p-benzoquinone imine (NAPQI). NAPQI is very reactive, with a high affinity for sulphydryl groups. The protein glutathione provides a ready source of available sulphydryl groups within the hepatocyte. When the liver’s glutathione stores are depleted and there are no longer sulphydryl groups available to detoxify this metabolite, it begins to react directly with the hepatocyte (see Fig. 45–1). In addition, the depletion of glutathione changes the mitochondrial oxidized to reduced glutathione ratio resulting in catastrophic shifts in mitochondrial function, accelerating cell necrocytolysis.\(^\text{13}\) Replenishing the liver’s sulphydryl capacity through the administration of N-acetylcysteine early after ingestion of the overdose halts this process.\(^\text{13}\) During the first hours after ingestion, some patients report mild symptoms of nausea and vomiting, but no elevations of the commonly measured liver enzymes are seen. Serum elevations in the liver enzymes begin 40 to 50 hours after ingestion.\(^\text{14}\)

Reye syndrome is an aggressive form of toxic hepatitis often associated with aspirin use in children. Valproic toxicity can also present in this pattern. Early in the process of Reye syndrome, mitochondrial dysfunction leads to the depletion of acyl-coenzyme A and carnitine. Fatty acids accumulate and gluconeogenesis is impaired, resulting in hypoglycemia. A concurrent disruption of the urea cycle occurs, leading to a decrease in the removal of ammonia and a slowing of protein use. A threefold rise in the blood ammonia level and an increase in the prothrombin time are common findings. In advanced stages of Reye’s syndrome, many patients develop intracranial hypertension that can be life-threatening and refractory to therapy.\(^\text{15,16}\)

**NONALCOHOLIC STEATOHEPATITIS**

Nonalcoholic steatohepatitis (NASH), also known as steatohepatitis and steatonecrosis, results from the accumulation of fatty acids in the hepatocyte. In the pre-acute stages this is known as nonalcoholic fatty liver disease (NAFLD). Drugs or their metabolites that cause NAFLD do so by affecting fatty-acid esterification and oxidation rates within the mitochondria of the hepatocyte (see Fig. 45–1). Hepatic vesicles become engorged with fatty acids, eventually disrupting hepatocyte homeostasis. In patients with diabetes, various dyslipidemias and even hypertension, the de novo production of free fatty acids from excess circulating carbohydrates, accelerates this process of accumulation. The liver biopsy is marked by a massive infiltration by polymorpho-nuclear leukocytes, degeneration of the hepatocytes, and the presence of Mallory bodies.\(^4\)

Alcohol is the drug that most commonly produces steatonecrotic changes in the liver. When alcohol is converted into acetaldehyde, the synthesis of fatty acids is increased.\(^7,18\) The hepatocyte can become completely engorged with microvesicular fat, resulting in alcoholic fatty liver. Metabolically this type of de novo free fatty acid synthesis depletes NADPH in favor of NADP\(^+\) and reduces the hepatocytes’ ability to respond to stress, bypassing normal apoptotic and increasing the rate of necrocytolysis. In NAFLD, the same end point is often achieved through oxidation of lipid peroxides.\(^6\)

If the offending agent is withdrawn before significant numbers of hepatocytes become necrotic, the process is completely reversible without long-term sequelae. If not, then ever increasing rates of necrocytolysis will induce an innate immune response and result in hepatitis.

Tetracycline produces NAFLD and NASH.\(^20\) The lesions are characterized by large vesicles of fat found diffused throughout the liver. The development of this reaction is related to the high concentrations achieved when tetracycline is given intravenously and in doses greater than 1.5 g/day. The mortality of tetracycline steatohepatitis is high (70%–80%), and those who do survive often develop cirrhosis. Sodium valproate also can produce steatonecrosis through the process of bioactivation.\(^1\) Cytochrome P450 converts valproate to delta-4-valproic acid, a potent inducer of microvesicular fat accumulation.\(^21\)

Patients experiencing steatohepatitis may present with abdominal fulness or pain as their only complaint. Patients with more severe steatonecrosis will present with all the symptoms characteristic of alcoholic hepatitis such as nausea, vomiting, steatorrhea, abdominal pain, pruritus, and fatigue.

**PHOSPHOLIPIDOSIS**

Phospholipidosis is the accumulation of phospholipids instead of fatty acids. The phospholipids usually engorge the lysosomal bodies of the hepatocyte.\(^22\) Amiodarone is associated with this reaction. Patients treated with amiodarone who develop overt hepatic disease tend to have received higher doses of the drug. These patients also have higher amiodarone-to-N-desethyl-amiodarone ratios, indicating a greater accumulation of the parent compound. Amiodarone and its major metabolite N-desethyl-amiodarone remain in the liver of all patients for several months after therapy is stopped. Usually the phospholipidosis develops in patients treated for more than 1 year. The patient can present with either elevated aminotransferases or hepatomegaly; jaundice is rare.\(^2,23\)

**GENERALIZED HEPATOCELLULAR NECROSIS**

Generalized hepatocellular necrosis mimics the changes associated with the more common viral hepatitis. The onset of symptoms is usually delayed as much as a week or more after exposure to toxin. Bioactivation is often important for toxic hepatitis to develop. Many drugs that are associated with toxic hepatitis produce metabolites that are not inherently toxic to the liver. Instead, they bind with proteins to create hapitens, which serve as neoantigens and induce the innate immune response (see Fig. 45–1).\(^31\)

1. The rate of bioactivation can vary between males and females and between individuals of the same sex.\(^25,26\) The superfamily of cytochrome P450 (CYP450) enzymes metabolize lipophilic substrates that are actively pumped into the hepatocyte by an organic anion (or cation) transporting protein. The CYP450 subspecies 2C, 2D, 3A, and 4A are regulated by the highly inducible xenobiotic receptor on complementary DNA. The receptor is found in the liver, and to a lesser extent in the cells lining the intestinal tract, and is responsible for cholesterol catabolism and bile acid homeostasis.\(^2\) The activity of this receptor is subject to genetic polymorphism. This results in a wide variation in the sensitivity of the population to hepatic damage.\(^27\)

The long-term administration of isoniazid can lead to hepatic dysfunction in 10% to 20% of those receiving the drug. Yet severe toxic hepatitis develops in only 1% or less of this population.\(^28\) The N-acetyltransferase 2 (NAT2) genotype appears to play a role in determining a patient’s relative risk. In one study, patients with the slow-type NAT2 genotype had a 28-fold greater risk of developing serum aminotransferase elevations than did patients with the fast-type NAT2 genotype.\(^29\) Isoniazid is metabolized by several pathways, acetylation being the major pathway. It is acetylated to
acetylisoniazid, which, in turn, is hydrolyzed to acetylhydrazine.\textsuperscript{30} The acetylhydrazine, and to a lesser extent the acetylisoniazid, are directly toxic to the cellular proteins in the hepatocyte, but rapid acylators detoxify acetylhydrazine very rapidly, converting it to diacetylhydrazine (a nontoxic metabolite). Therefore, it is the rate and efficiency of this reaction sequence that ultimately determines if hepatocellular damage will ensue.

Isoniazid simultaneously is an example of the potential predictability of drug-induced liver disease based on single nucleotide polymorphism and a lesson in the limitations of our current understanding.\textsuperscript{3} There are definite links to NAT2 genotype and toxicity.\textsuperscript{31} The risk for this reaction is also influenced heavily by the age of the patient, with older patients having a much higher risk than younger patients. In fact, age may be more important than genotype.\textsuperscript{3,28,31} In one prospective series focused on drug-induced liver disease, cases involving isoniazid had a median onset at 6 months of therapy with around 30% of isoniazid-induced liver disease clustered between 6 to 8 months.\textsuperscript{7}

Ketoconazole produces generalized hepatocellular necrosis or milder forms of hepatic dysfunction in 1% to 2% of patients treated for fungal infections. The onset is usually early in therapy. In immunocompromised patients in whom ketoconazole is used, special care should be taken to watch for changes in liver function.\textsuperscript{32}

**TOXIC CIRRHOSIS**

The scarring effect of hepatitis in the liver leads to the development of cirrhosis. Some drugs tend to cause such a mild case of hepatitis that it may not be detected. Mild hepatitis can be easily mistaken for a more routine generalized viral infection. If the offending drug or agent is not discontinued, this damage will continue to progress. The patient eventually presents not with hepatitis, but with cirrhosis.

Methotrexate causes periportal fibrosis in most patients who experience hepatotoxicity.\textsuperscript{1} The lesion results from the action of a bioactivated metabolite produced by CYP450.\textsuperscript{33} This process occurs most commonly in patients treated for psoriasis and arthritis.

The extent of damage can be reduced or controlled by increasing the dosage interval to once weekly or by routine use of folic acid supplements.\textsuperscript{33} Vitamin A is normally stored in liver cells, and causes significant hypertrophy and fibrosis when taken for long periods in high doses. Hepatomegaly is a common finding, along with ascites and portal hypertension. In patients with vitamin A toxicity, gingivitis and dry skin are also very common. This is accelerated by ethanol, which competes with retinol for aldehyde dehydrogenase.\textsuperscript{17}

**CHOLESTATIC INJURY**

A second pattern of hepatic damage is an injury that primarily involves the bile canaliculal system and is known as cholestatic injury. Cholestatic disease is more often seen in patients over the age of 60 and is slightly more common in males.\textsuperscript{34} In cholestatic disease, disturbance of the subcellular actin filaments around the canaliculi prevents the movement of bile through the canalicular system.\textsuperscript{35} The inability of the liver to remove bile causes intrahepatic accumulation of toxic bile acids and excretion products.\textsuperscript{36} Although rare, some patients develop progressive destruction of the cholangiocytes leading to the vanishing bile duct syndrome.

Drug-induced cholestasis can occur as an acute disorder (e.g., cholestasis with or without hepatitis and cholestasis with bile duct injury) or as a chronic disorder (e.g., vanishing bile duct syndrome, sclerosing cholangitis, and cholelithiasis).\textsuperscript{37} However, the most common form of drug-induced cholestasis is cholestasis with hepatitis. Most patients with this acute disorder present with nausea, malaise, jaundice, and pruritus.\textsuperscript{8} Elevations in serum alkaline phosphatase levels are more prominent and usually precede the elevations of other liver enzymes in serum.\textsuperscript{9} A liver biopsy is not usually required, but is sometimes pursued when other causes of cholestatic disease are suspected.\textsuperscript{38} Although the antipsychotic drug chlorpromazine appears to be the prototype drug for this disorder, other medications are associated with other forms of cholestatic injury, such as erythromycin estolate, amoxicillin-clavulanic acid, and carbamazepine.\textsuperscript{8}

Cholestatic injury, also known as cholestatic jaundice or cholestasis, can be classified by the area of the bile canalicular or ductal system that is impaired. Canalicular cholestasis is often associated with long-term, high-dose estrogen therapy. These patients are often asymptomatic and present with mild to moderate elevations of serum bilirubin.\textsuperscript{39} An intravenous form of vitamin E, α-tocopherol acetate, causes cholestatic jaundice, primarily involving the canalicular duct in premature infants. The incidence of this reaction in those receiving this formulation was high (>10%) and the mortality even higher (>50%).\textsuperscript{40}

The administration of total parenteral nutrition for periods greater than 1 week induces cholestatic changes and nonspecific enzyme elevations in some patients. Patients with low serum albumin concentrations may be at greater risk than patients with normal serum albumin concentrations.\textsuperscript{3} This reaction also has been reported to occur rarely with sulfonamides, sulfonyleureas, erythromycin estolate and ethylsuccinate, captopril, lisinopril, and other phenothiazines.\textsuperscript{41}

**LIVER VASCULAR DISORDERS**

Focal lesions in hepatic venules, sinusoids, and portal veins occur with various drugs. The most commonly associated drugs are the cytotoxic agents used to treat cancer, the pyrrolizidine alkaloids, and the sex hormones. A centralized necrosis often follows and can result in cirrhosis. Azathioprine and herbal teas that contain comfrey (a source of pyrrolizidine alkaloids) are associated with the development of venoocclusive disease. The exact incidence is rare and may be dose related.\textsuperscript{4} Peliosis hepatitis is a rare type of hepatic vascular lesion that can be seen as both an acute and a chronic disease. The liver develops large, blood-filled lacunae (space or cavity) within the parenchyma. Rupture of the lacunae can lead to severe peritoneal hemorrhage. Peliosis hepatitis is associated with exposure of the liver to androgens, estrogens, tamoxifen, azathioprine, and danazol. Androgens with a methyl alkylation at the 17-carbon position of the testosterone structure are the most frequently reported agents that cause peliosis hepatitis, usually after at least 6 months of therapy.\textsuperscript{42}

**STIMULATION OF AUTOIMMUNITY**

Autoimmune injuries involve antibody mediated cytotoxicity or direct cellular toxicity.\textsuperscript{34,43} This type of injury occurs when enzyme drug adducts migrate to the cell surface and form neoantigens. The
liver plays host to all of the cells that make up the innate immune response system in the body along with Kupffer cells which are a type of macrophage. These cells sit in anticipation around the hepatocytes, in the space of Disse and elsewhere waiting for antigens (or neoantigens) to present themselves. The neoantigens serve as targets for cytolytic attack by killer T-cells, and others. Halothane, sulfamethoxazole, carbamazepine, and nevirapine are associated with autoimmune injuries. Stimulation of autoimmunity is often associated with fulminant presentations.

Dantrolene,isoniazid,phenytoin,nitrofurantoin,andtrazodone are associated with a type of autoimmune-mediated disease in the liver called chronic active hepatitis. Patients experience periods of symptomatic hepatitis followed by periods of convalescence, only to repeat the experience months later. It is a progressive disease with a high mortality rate and is more common in females than males. Antinuclear antibodies appear in most patients. These drugs appear to form antiangielle antibodies. The exact identification of a causative agent is sometimes difficult as diagnosis requires multiple episodes occurring long after exposure to the offending drug.

**IDIOSYNCRATIC REACTIONS**

Idiosyncratic drug-related hepatotoxicity is rare and usually occurs in a small proportion of individuals. These adverse reactions are often categorized into allergic and nonallergic reactions. The allergic reactions are characterized by fever, rash, and eosinophilia. They are usually dose-related and have a short latency period (<1 month). Upon reexposure to the offending agent, the patient will experience rapid recurrence of hepatotoxicity. Studies show that minocycline, nitrofurantoin, and phenytoin can cause allergic reactions.

Unlike the allergic reactions, the nonallergic idiosyncratic reactions are devoid of the hypersensitivity features and usually have a long latency period (several months). These patients often have normal liver function tests for 6 months or longer and then suddenly develop hepatotoxicity. Dependent on the medication, the hepatotoxicity may be associated with autoimmune injuries. Stimulation of autoimmunity is often associated with fulminant presentations.

**DISRUPTION OF CALCIUM HOMEOSTASIS AND CELL MEMBRANE INJURY**

Drug-induced damage to the cellular proteins that are involved with calcium homeostasis can lead to an influx of intracellular calcium that causes a decline in adenosine triphosphate levels and disruption of the actin fibril assembly. The resulting impact on the cell is blebbing of the cell membrane, rupture, and cell lysis. Lovastatin, venlafaxine, and phalloidin, which is the active component of mushrooms, impair calcium homeostasis.

**METABOLIC ACTIVATION OF THE CYTOCHROME P450 ENZYMES**

Most hepatocellular injuries involve the production of high-energy reactive metabolites by the CYP450 system. These reactive metabolites are capable of forming covalent bonds with cellular proteins (enzymes) and nucleic acids that lead to adduct formation. In the case of acute toxicity, the enzyme-drug adduct can cause cell injury or cell lysis. Adducts that form with DNA can cause long-term consequences such as neoplasia. Acetaminophen, furosemide, and diclofenac are examples of this mechanism of liver injury.

Individual genetic differences can play a role in the significance of this process. Patients with a single nucleotide polymorphism (SNP) that codes for slow-reacting variants of CYP450 will react differently from those with a SNP that codes for very fast-reacting variants.

**STIMULATION OF APOPTOSIS**

Apoptosis represents a distinct pattern of cell lysis that is characterized by cell shrinkage and fragmentation of nuclear chromatin. Apoptotic pathways are triggered by interactions between death ligands (tumor necrosis factor and Fas ligand) and death receptors (tumor necrosis factor receptor 1 and Fas). These interactions activate caspases which cleave cellular proteins and eventually lead to cell death. Cumulative doses of acetaminophen cause apoptosis.

**MITOCHONDRIAL INJURY**

Drugs that impair mitochondrial structure, function, or DNA synthesis can disrupt β-oxidation of lipids and oxidative energy production within the hepatocyte. In acute disease, prolonged interruption of β-oxidation leads to microvesicular steatosis, whereas, in chronic disease, macrovesicular disease is present. Severe damage to the mitochondria eventually leads to hepatic failure and death. Aspirin, valproic acid, and tetracycline cause mitochondrial injury by inhibiting β-oxidation and amiodarone via disruption of oxidative phosphorylation.

**LIVER NEOPLASTIC DISEASE**

A large body of the current literature on adverse reactions and the liver addresses the development of neoplasms following drug therapy. Both carcinoma- and sarcoma-like lesions have been identified. Fortunately, hepatic tumors associated with drug therapy are usually benign and remit when drug therapy is discontinued. Except in rare instances, these lesions are associated with long-term exposure to the offending agent. Androgens, estrogens, and other hormonal-related agents are the most frequently associated causes of neoplastic disease. The model for drug-induced hepatic cancer is polyvinyl chloride exposure. Used in the production of many types of plastic products, polyvinyl chloride induces angiosarcoma in exposed workers after as few as 3 years of exposure.

**ASSESSMENT**

The best and most important technique for assessing and monitoring drug-induced liver disease is the patient’s history. Questions addressing the patient’s drug use along with a thorough review of systems are essential. The use of a protocol, such as that proposed by Danan and Benichou, can significantly improve the accuracy of the assessment (Table 45-1). Drugs for recreational purposes must not be overlooked. Cocaine has been directly linked to liver disease. Ecstasy, the street name of methylenedioxymethamphetamine, has induced fulminant hepatitis, which has led to death in some cases. The more pervasive impact of street drugs on the incidence of hepatic disease is the concomitant injection or ingestion of adulterants. Many of these adulterants are either directly toxic or serve to enhance the toxicity of the drug.

It is also important to determine nondrug hepatic disease risk from occupational or environmental exposure. Arsenic, for example, is known to induce both acute and chronic hepatic reactions. Even if exposure to an environmental toxin does not produce a hepatic reaction, it may predispose a patient to a hepatic reaction when a drug is added. Table 45-2 lists some of the more common hepatic toxins found in occupational or environmental exposures that can add to the risk for developing a hepatic lesion. Immune-mediated chronic liver diseases can often be tracked to geographic clusters that correspond to known toxic waste sites around the world.

The likelihood that this presentation is an adverse reaction in the liver increases linearly with an increasing score. The maximum score is 14, and scores below 7 are associated with an ever decreasing likelihood that the drug or drug combination in question caused the problem. This approach is not designed for the assessment of hepatic cancers or cirrhotic conditions. Reprinted from J Clin Epidemiol, Vol 46, Danan G, Benichou C. Causality assessment of adverse reactions to drugs—1. A novel method based on the conclusions of international consensus meetings: Application to drug-induced liver injuries: pages 1323–1330, Copyright 1993, with permission from Elsevier.

A person’s use of alternative medicine must be solicited. In the prospective series of cases noted earlier, from an area of the country where traditional medicine usage is commonplace, herbal remedies and other traditional medicines accounted for 14 of 132 cases of drug-induced liver disease. Comfrey tea is a common cause of hepatocellular damage. As in the case of the Chinese remedy jin bu huan, or as in the case of the more elegantly presented chaparrell capsules containing grease wood leaves, the end of therapy with these types of agents is occasionally severe disability or death from fulminant hepatic failure. Low serum levels of vitamins E and C, along with lutein and the α- and β-carotenes are associated with asymptomatic elevations in transaminases. Conversely, high serum iron, transferrin, and selenium levels are also associated with asymptomatic elevations of transaminases. All potential drug reactions should be judged as to the timing of the reaction versus drug administration, pharmacokinetic considerations, the information in the literature records about previous reactions, the inclusion of alternative nondrug causes, and close clinical observation when the drug in question is stopped. It is also important to keep in mind that most elevations in liver enzymes will not be associated with a drug. In a study of all patients admitted to a hospital in the United Kingdom with elevated liver aminotransferases, only 9% of cases involved a drug other than alcohol as the possible cause. In all cases, titers of serum antibodies to hepatitis A, B, and C should be drawn. Even in cases in which the drug is absolutely targeted as the cause, viral hepatitis may be a complication.

Often there is no good clinical test available to determine the exact type of hepatic lesion, short of liver biopsy. There are certain patterns of enzyme elevation that have been identified and can be helpful (Table 45–3). The specificity of any serum enzyme depends on the distribution of that enzyme in the body. Alkaline phosphatase is found in the bile duct epithelium, bone, and intestinal and kidney cells. 5’-Nucleotidase is more specific for hepatic disease than alkaline phosphatase, because most of the body’s store of 5’-nucleotidase is in the liver. Glutamate dehydrogenase is a good indicator of centrolobular necrosis because it is found primarily in centrolobular mitochondria. Most hepatic cells have extremely high concentrations of transaminases. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are commonly measured in serum. Because of their high concentrations and easy liberation from the hepatocyte cytoplasm, AST and ALT are sensitive indicators of necrotic lesions within the liver. After an acute hepatic lesion is established, it may take weeks for these concentrations to return to normal.

Serum bilirubin concentration is a sensitive indicator of most hepatic lesions and has significant prognostic value. High peak bilirubin concentrations are associated with poor survival. Other important findings that indicate poor survival are a peak prothrombin time greater than 40 seconds, elevated serum creatinine, and low arterial pH. The presence of encephalopathy or prolonged jaundice are not good signs for the survival of the patient and are strong indicators for transplantation. Bilirubin concentrations and serum enzyme elevations give a static picture of the liver’s condition and are not good indicators of hepatic function. Clinically available tests to predict hepatic function include measurement of serum proteins (albumin or transferrin). As a hepatic function decreases, serum protein concentrations in the body decrease at a rate determined by each protein’s own elimination rate. Overhydration and starvation can also decrease serum protein concentrations. Changes in the prothrombin time often occur earlier than the changes in albumin or transferrin. The response of the prothrombin time to the administration of 10 mg of parenteral vitamin K is often used to differentiate between hepatic and extrahepatic disease.
MEASUREMENT OF LIVER FUNCTION

A good compound for a liver function test would theoretically be (a) nontoxic and lacking any pharmacologic effect; (b) either rapidly and completely absorbed orally or easily administered via a peripheral vein; (c) eliminated only by the liver; and (d) easily measured (drug and its metabolite) in blood, saliva, or urine. Several tests are used in research settings and in liver transplant patients to indicate liver function. Tests such as sulfobromophthalein, indocyanine green, or sorbitol measure qualities of hepatic clearance. There are also a few drugs that have been used to test liver function. The advantage of sorbitol over indocyanine green is a much lower incidence of allergic reactions. It is partially cleared by the kidney, and urine levels must also be determined during the test. A good estimate of hepatic clearance can be obtained by serial blood levels of a variety of hepatically eliminated drugs if an assay is locally available. Ultrasound and computed tomographic imaging can be used on a periodic basis to monitor for the development of fibrosis or vascular lesions in the liver and for hepatocellular carcinomas.

If a liver biopsy has been performed, the injury should be classified by the histologic findings. In cases in which there is no biopsy, the pattern of liver enzyme elevation can estimate the type of injury. Hepatocellular injuries are marked by elevations in transaminase that are at least two times normal. If the alkaline phosphatase is also elevated, a hepatocellular lesion is still suspected when the elevation of ALT is notably higher than the elevation of alkaline phosphatase. If the magnitude of elevation is nearly equal between ALT and alkaline phosphatase, the lesion is likely cholestatic.

A liver injury is acute if it lasts less than 3 months; it is considered chronic after 3 months of consistent symptoms or enzyme elevation. A liver injury is severe if the patient has marked jaundice, if the prothrombin time does not improve by more than 50% after the administration of vitamin K, or if encephalopathy is detectable. If an acute liver injury progresses from normal to severe in a matter of a few days or weeks, it is considered fulminant.

The serum transaminases AST and ALT are the most commonly used transaminases in the clinical setting. There are often no set rules available for a particular drug. The general guidelines found in Table 45-4 can help in determining a monitoring schedule for drugs where no prior recommendations are published. Concentrations of these enzymes should be obtained approximately every 4 weeks, depending on the reported characteristics of the reaction in question. Methotrexate should be monitored every 4 weeks, because toxicity usually develops over a period of several weeks to months. In addition, some recommend that sulfobromophthalein or indocyanine green excretion studies be performed on a regular basis and that patients treated for very long periods of time should have a liver biopsy performed every 12 months.

NAT2: Non-alcoholik steatohepatitis

REFERENCES

This page intentionally left blank
Pancreatitis is inflammation of the pancreas with variable involvement of regional tissues or remote organ systems. Acute pancreatitis is characterized by severe pain in the upper abdomen and elevations of pancreatic enzymes in the blood. In the majority of patients, acute pancreatitis is a mild, self-limiting disease that resolves spontaneously without complications. Approximately 20% of adults have a severe course, and 10% to 30% of those with severe acute pancreatitis die. Although exocrine and endocrine pancreatic function may remain impaired for variable periods after an attack, acute pancreatitis seldom progresses to chronic pancreatitis.

Chronic pancreatitis is characterized by long-standing inflammation that eventually leads to a loss of pancreatic exocrine and endocrine function. It is a progressive disease that often goes unnoticed for many years. Usually patients first present with complaints of chronic abdominal pain. Later in the disease process malabsorption with resultant steatorrhea occurs. This leads to malnutrition and weight loss. Finally, patients develop diabetes mellitus due to a loss of pancreatic endocrine function.

**Epidemiology**

The prevalence of pancreatitis varies widely with geographic, etiologic (e.g., alcohol consumption), environmental, and genetic factors. The reported prevalence of acute pancreatitis among men and women in the United States is less than 1%. Approximately six per 100,000 population will develop chronic pancreatitis with a peak incidence between ages 35 and 54 and about 85% of cases occurring in men. However, this incidence may be underestimated due to diagnostic difficulties and various classification systems. Also, the prevalence of chronic pancreatitis varies widely based on geographic location. Hospitalizations for acute pancreatitis have increased in the United States, most likely related to an increase in gallstones in association with obesity. The incidence of gallstone-related acute pancreatitis has increased among white women older than age 60 years. Hospitalization for chronic pancreatitis has also doubled in the past decade, with black patients being almost two to three times as likely to be hospitalized for chronic pancreatitis than for alcoholic cirrhosis.

**Pancreatic Exocrine Physiology**

The pancreas possesses both endocrine and exocrine functions. The islets of Langerhans, which contain the cells of the endocrine pancreas, secrete insulin, glucagon, somatostatin, and other polypeptide hormones. The exocrine pancreas is composed of acini and ductules that secrete about 2.5 L/day of isotonic fluid that contains water, electrolytes, and pancreatic enzymes necessary for digestion. Bicarbonate and other electrolytes are secreted primarily by
the centroacinar (ductular) cells in order to neutralize gastric acid. Pancreatic juice is delivered to the duodenum via the pancreatic ducts (Fig. 46–1) where the alkaline secretion neutralizes gastric acid and provides an appropriate pH for maintaining the activity of pancreatic enzymes.\(^\text{10}\)

The major pancreatic exocrine enzyme groups are as follows:

- Amylolytic: amylase
- Lipolytic: lipase, procolipase, phospholipase A\(_2\), and carboxylesterase
- Proteolytic: trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase
- Nucleolytic: ribonuclease, deoxyribonuclease
- Other: trypsin inhibitor

Amylase is responsible for digestion of starches and glycogen through hydrolysis. The lipolytic enzymes break down triglycerides, cholesterol, and other fats in the digestive tract. Specifically, lipase hydrolyzes triglycerides into fatty acids and monoglycerides. Colipase and bile acids facilitate this process by allowing lipase to act on the hydrophobic surface of fat droplets in the mainly hydrophilic environment. Phospholipase A\(_2\) and carboxylesterase continue to break down fatty acids, cholesterol, monoglycerides, and other products of fat digestion. Proteolytic enzymes digest proteins into oligopeptides and free amino acids, while nucleases break down nucleic acids.\(^\text{10,11}\)

The production of proteolytic enzymes in the pancreas occurs in a manner that prevents self-digestion of the pancreas. These enzymes are synthesized within the acinar cells and secreted into the duodenum aszymogens (inactive enzymes). Enterokinase secreted by the duodenal mucosa converts trypsinogen to trypsin, which then activates all other proteolyticzymogens along with procolipase and phospholipase A\(_2\). Thus two important mechanisms protect the pancreas from the potential degradative action of its own digestive enzymes. First, the synthesis of proteolytic enzymes aszymogens requires extrapancreatic activation by trypsin. Second, pancreatic juice contains a low concentration of trypsin inhibitor, which inactivates any autocatalytically formed trypsin within the pancreas. Proteolytic activity of trypsin in the intestinal lumen is not inhibited because the concentration of trypsin inhibitor is minimal. Lipase, amylase, ribonuclease, and deoxyribonuclease are secreted by the acinar cells in their active form.\(^\text{10}\)

The regulation of exocrine pancreatic secretion is a complex interplay of neurohormonal feedback with three distinct phases. The first phase is the cephalic phase where the sight, smell, and taste of food produce pancreatic enzyme secretion through stimulation of the vagus nerve. Vasoactive intestinal peptide (VIP) and gastrin-releasing peptide (GRP) released from efferent vagus nerve terminals bind to receptors on the acinar cells stimulating enzyme release.\(^\text{10}\) Water and bicarbonate are also released from ductal cells due to VIP stimulation. The gastric phase occurs due to gastric distension from food entering the stomach. This results primarily in secretion of digestive enzymes from the pancreas. Once chyme enters the duodenum the intestinal phase begins. The chyme causes secretion to be released from the duodenal mucosa when its pH is less than 4.5. Secretin results in water and bicarbonate secretion from the pancreas, which is necessary since lipolytic enzymes are inactivated at a pH below 5.\(^\text{11}\) Digestive enzymes are released from the pancreas due to the presence of fatty acids, peptides, amino acids, and glucose in the duodenum.\(^\text{10}\)

The feedback mechanism for continued release of pancreatic enzymes involves the hormone cholecystokinin (CCK). When products of fat, protein, and starch digestion enter the upper small intestine they stimulate release of CCK from I cells into the blood. Elevated levels of CCK in the serum activate a vagovagal reflex causing further release of VIP and GRP, leading to enhanced pancreatic enzyme secretion. Inhibition of this feedback loop is thought to be due to trypsin. After digestion is complete unoccupied trypsin is thought to inhibit the release of CCK.\(^\text{10}\) A more in-depth discussion of pancreatic physiology can be found elsewhere.\(^\text{10}\)

### ACUTE PANCREATITIS

Acute pancreatitis varies from mild to severe disease. The morphological appearance of the pancreas and surrounding tissue ranges from interstitial edema and inflammatory cells (interstitial pancreatitis) to pancreatic and extrapancreatic necrosis (necrotizing pancreatitis). Necrotizing pancreatitis has a higher risk of infection, organ failure, and mortality.\(^\text{2}\) The rupture of blood vessels within or around the pancreas can also lead to a collection of blood in the retroperitoneal space.

### ETIOLOGY

Table 46–1 lists the etiologic risk factors associated with acute pancreatitis. Obstruction caused by gallstones is the most common

cause of acute pancreatitis and alcohol abuse the second; together they account for 70% to 80% of all cases of acute pancreatitis. There has been an increase in identification of genetic and autoimmune causes of acute pancreatitis. Most of the remaining cases are idiopathic. Acute pancreatitis occurs in 1.8% to 7.2% of all patients who have undergone endoscopic retrograde cholangiopancreatography (ERCP), and in 30% to 40% of high-risk patients. End-stage kidney disease increases the risk of acute pancreatitis, with patients who are receiving chronic peritoneal dialysis being at higher risk than those receiving hemodialysis. Cigarette smoking appears to increase the risk of pancreatitis, especially in alcohol-related disease. Pregnancy is not considered a cause of acute pancreatitis; however, pregnant women develop pancreatitis as a result of a coincident process, most commonly cholelithiasis. In pediatric patients, the common etiologies are systemic illness, biliary disease, trauma, and medications.

**Medications**

Drug-induced acute pancreatitis should be suspected when other causes have been excluded and there is a temporal relationship with the initiation of a medication that has been implicated as a cause. The percentage of acute pancreatitis cases caused by medications ranges from a few months to several years, with a median of 5 weeks; onset after rechallenge can occur within hours. The onset may differ according to the mechanism. Clinicians should be especially suspicious of drug-induced acute pancreatitis in high-risk patients, such as those receiving multiple medications or immunomodulating drugs, and in geriatric, HIV-positive, and cancer patients.

Numerous drugs are believed to cause acute pancreatitis, but ethical and practical considerations prevent rechallenge with suspected agents. Table 46–2 lists specific agents associated with acute pancreatitis based on known association. Class I (definite association) implies a temporal relationship of drug administration to abdominal pain and hyperamylasemia in at least 20 reported cases with at least one positive response to rechallenge with the offending agent. Class II medications are implicated in more than ten, but less than 20, reported cases of acute pancreatitis and suggest a probable association. Class III includes medications with a possible association, defined as fewer than 10 published cases or unpublished reports in pharmaceutical or U.S. Food and Drug Administration files. A comprehensive list of class III drugs can be found elsewhere.

Mechanisms of drug-induced pancreatitis are not clearly defined but may fall into several general categories, including direct toxic effects of the drug or its metabolites, hypersensitivity, drug-induced hypertriglyceridemia, and alterations of cellular function in the pancreas and pancreatic duct. Once the process is initiated, disease severity is determined by the propagation of proinflammatory mediators. Although acute pancreatitis is an infrequent complication of drug therapy it is prudent to withdraw medication when an association is suspected.

**PATHOPHYSIOLOGY**

The pathophysiology of acute pancreatitis is based on events that initiate injury and secondary events that establish and perpetuate the injury (Fig. 46–2). Alcohol abuse and gallstones cause different
Gastrointestinal Disorders

SECTION 4

initial insults to the pancreas. However, acute pancreatitis of any etiology involves the premature activation of trypsinogen to trypsin within the pancreas, leading to activation of other digestive enzymes and autodigestion of the gland. The lysosomal protease, cathepsin B, and intracellular calcium may be involved in the activation of trypsinogen as well as decreased activity of trypsin inhibitor. Genetic abnormalities in pathways that protect the pancreas from autodigestion also play a pathophysiologic role in the development of some forms of acute pancreatitis, and may be the differentiating factor in the minority of alcoholics that develop disease.

In addition to increased production, activated enzymes are retained in the acinar cells in higher concentrations than normal. Activated pancreatic enzymes released into the pancreas and surrounding tissues produce damage and necrosis to the pancreatic tissue, the surrounding fat, the vascular endothelium, and adjacent structures. Lipase damages the fat cells, producing noxious substances that cause further pancreatic and peripancreatic injury. The release of cytokines by acinar cells directly causes their injury and enhances the inflammatory response. Injured acinar cells liberate chemoattractants that recruit neutrophils, macrophages, and other cells to the area of inflammation. These immune responses cause a systemic inflammatory response syndrome (SIRS). Vascular damage and ischemia cause the release of kinins, which make capillary walls permeable and promote tissue edema. The release of damaging oxygen-free radicals appears to correlate with the severity of pancreatic injury. Finally, pancreatic infection may result from increased intestinal permeability and translocation of colonic bacteria.

COMPLICATIONS

Early complications are a result of fluid losses and SIRS. Hypotension results from hypovolemia, hypoalbuminemia, the release of kinins, and sepsis. Even patients with mild disease have significant fluid losses. Renal complications are usually caused by hypovolemia. Pulmonary complications develop when fluid accumulates within the pleural space compressing the lungs, and with development of the acute respiratory distress syndrome (ARDS), which limits gas exchange. The differential diagnosis for hypoxemia should include ARDS in patients with acute pancreatitis who do not have a history of pulmonary disease. Pleural effusions occur in 4% to 17% of patients, more frequently on the left. Gastrointestinal bleeding occurs secondary to numerous causes, including rupture of a pseudocyst (collection of pancreatic secretions and tissue debris enclosed by a wall of fibrous or granulation tissue). Severe acute pancreatitis is also associated with confusion and coma.

Local complications including acute fluid collection, pancreatic necrosis, infection, abscess (collection of pus in or adjacent to the pancreas), and pseudocyst develop approximately 3 to 4 weeks after the initial attack. Pancreatic infections occur in 15% to 30% of those with pancreatic necrosis and are usually secondary infections of necrotic tissue. Pancreatic ascites occur when pancreatic secretions spread throughout the peritoneal cavity. Systemic complications include cardiovascular, renal, pulmonary, metabolic, hemorrhagic, and central nervous system abnormalities. Long-term complications include cardiovascular, renal, pulmonary, metabolic, hemorrhagic, and central nervous system abnormalities.

CLINICAL PRESENTATION

Signs and Symptoms

The clinical presentation of acute pancreatitis varies depending on the severity of the inflammatory process and whether damage is confined to the pancreas or involves local and systemic complications (Table 46–3).

Diagnosis

Most guidelines agree that the diagnosis should be made within 48 hours based on characteristic abdominal pain and amylase, lipase, or both being elevated to at least three times the upper limit of normal. Lipase is more sensitive and specific than amylase and is preferred. Contrast-enhanced computed tomography (CECT) of the abdomen may be used to confirm the diagnosis, including in patients with any amylase or lipase levels that are not three times the upper limit of normal. Some guidelines consider ultrasonography to be an acceptable alternative to CECT. However, it is best used to ascertain the presence of gallstones. The diagnosis of acute pancreatitis should also be considered when evaluating patients with SIRS (see Table 46–3). For further information on laboratory tests and abdominal imaging refer to Table 46–3.

Prediction of Disease Severity

Prediction of severity of acute pancreatitis is useful for decisions involving the need for aggressive treatment, including admission to intensive care units. The risk for severe acute pancreatitis should be assessed upon admission and on an ongoing basis. Several recognized scoring systems have been developed to assess the likelihood of severe disease (Table 46–4). However, development and validation of such systems remains an ongoing area of research. The Ranson criteria scoring system was developed for pancreatitis and assesses 11 variables that must be monitored at the time of admission and during the initial 48 hours of hospitalization. Severe acute pancreatitis is characterized by three or more criteria. Patients with fewer than three Ranson criteria have a mortality rate of less than 1%, whereas those with six or more have a 100% mortality rate. The Ranson criteria are complete only after 48 hours. The Atlanta scoring system was developed based on consensus opinions; it consolidates clinical indicators, organ failure, and local complications to provide an ongoing assessment of disease severity. The Acute Physiology and Chronic Health Evaluation II (APACHE II) system uses 12 indicators of physiologic and biochemical function, age, and previous health status to predict mortality in critically ill patients, but it is not specific to pancreatitis. The APACHE II score is calculated within the first 24 hours and is considered among the best predictors of severity on admission. A score greater than or equal to 8 points is considered the threshold for severe acute pancreatitis. A modification, called the APACHE-O, improves predictive value in acute pancreatitis by adding points for a body mass index of 26 kg/m2 or more.
CHAPTER 46
ACUTE PANCREATITIS

CLINICAL COURSE AND PROGNOSIS

The clinical course of acute pancreatitis varies from a mild transitory disorder to a severe necrotizing disease. Mild acute pancreatitis is self-limiting and subsides spontaneously within 3 to 5 days. Mortality increases with unfavorable early prognostic signs, local complications, and organ failure. Pancreatic necrosis carries a 10% mortality, but this increases to 30% to 40% with infected necrosis. Mortality is influenced by etiology, as idiopathic and postoperative acute pancreatitis have higher rates than gallstone- or alcoholically-induced disease. First and second occurrences also carry a higher mortality than subsequent episodes. Death during the first few days results from SIRS and multiorgan failure. When death occurs after this period, it is usually a result of infected necrosis, pancreatic abscess, and sepsis.

TREATMENT

Acute Pancreatitis

**DESIRED OUTCOME**

Treatment of acute pancreatitis is aimed at relieving abdominal pain and nausea, replacing fluids, correcting electrolyte, glucose, and lipid abnormalities, minimizing systemic complications, and preventing pancreatic necrosis and infection. Management varies depending on the severity of the attack (Fig. 46–3). Patients with mild acute pancreatitis respond very well to the initiation of supportive care and the reduction of pancreatic secretions. Patients with severe acute pancreatitis should be treated aggressively and monitored closely.

### GENERAL APPROACH TO TREATMENT

All patients with acute pancreatitis should receive supportive care, including intravenous fluid resuscitation, adequate nutrition, and effective relief of pain and nausea. The use of nasogastric aspiration offers no clear advantage in patients with mild acute pancreatitis, but it is beneficial in patients with profound pain, severe disease, paralytic ileus, and intractable vomiting. Patients predicted to follow a severe course will require treatment of cardiovascular, respiratory, renal, and metabolic complications. Aggressive fluid resuscitation is essential to correct intravascular volume depletion. However, specific recommendations cannot be made from the current literature, and this is a subject of ongoing research. The prognosis of the patient often depends on the rapidity and adequacy of volume restoration, as large quantities of fluid are sequestered within the peritoneal and retroperitoneal spaces. Vasodilatation from the inflammatory response, vomiting, and nasogastric suction contributes to hypovolemia and fluid and electrolyte abnormalities. Intravenous colloids may be required to maintain intravascular volume and blood pressure because fluid losses are high in protein. Patients with pancreatitis and SIRS should be treated according to SIRS guidelines. Intravenous potassium, calcium, and magnesium are used to correct electrolyte deficiency states. Insulin is used to treat hyperglycemia. Local complications resolve as the inflammatory process subsides. However, patients with necrotizing pancreatitis may require antibiotics and surgical intervention. Medications listed in Table 46–2 should be discontinued if possible.

### NONPHARMACOLOGIC THERAPY

Nonpharmacologic therapy includes ERCP for removal of any underlying biliary tract stones, surgery, and nutritional support. Surgery is indicated in patients with pancreatic pseudocyst or abscess or to drain the pancreatic bed if hemorrhagic or necrotic material is present. The need for admission to an intensive care unit should also be addressed.

### Nutrition and Probiotics

Nutritional support plays an important role in the management of patients with mild or severe disease as acute pancreatitis creates a catabolic state that promotes nutritional depletion. This can impair recovery, increase the risk of complications, and prolong hospitalization. Patients with mild acute pancreatitis can begin oral feeding when bowel sounds have returned and pain has resolved. In severe or complicated disease, nutritional deficits develop rapidly and are complicated by tissue necrosis, organ failure, and surgery. Nutritional support should begin when it is anticipated that oral nutrition will be withheld for more than 1 week. In the past, there was concern that enteral feeding stimulated pancreatic enzyme secretion and exacerbated the underlying disease. However, numerous studies have shown that enteral feeding in severe acute pancreatitis is as safe and effective as parenteral nutrition, attenuates the acute inflammatory response, and improves disease severity. The mechanisms for this include protection of the gut barrier and prevention of colonization with pathogenic bacteria, both of which may prevent translocation of bacteria and infection. Therefore, the enteral route is preferred over the parenteral in patients with severe acute pancreatitis, provided that it can be tolerated. More specifically, the nasojejunal route may be preferred, but the nasogastric route also appears to be safe and effective. If enteral feeding is not possible or if the patient is unable to obtain sufficient nutrients, parenteral nutrition should be implemented before protein and calorie depletion become advanced. Intravenous lipids should not be withheld unless the serum triglyceride concentration is greater than 500 mg/dL. Preliminary data suggest that the early nasojejunal administration of probiotics, such as lactobacillus, with enteral nutrition may reduce bacterial translocation and possibly decrease pancreatic necrosis and abscess.

### PHARMACOLOGIC THERAPY

#### Recommendations

Besides fluid resuscitation and nutritional support patients with acute pancreatitis require treatment for pain and nausea. Pain and nausea can be treated with intravenous analgesics and antiemetics. Antisecretory agents may be used to prevent stress-related mucosal bleeding. Octreotide may be tried in severe acute pancreatitis, but its efficacy remains uncertain. The use of prophylactic antibiotics is controversial and most guidelines do not support this practice.

#### Relief of Abdominal Pain

Parenteral opioid analgesics are used to control abdominal pain associated with acute pancreatitis. The most important factors to consider in selecting an analgesic are efficacy and safety.
are not deleterious to the patient. Traditionally, treatment was initiated with parenteral meperidine (50 to 100 mg every 3 to 4 hours) because it did not significantly alter the function of the sphincter of Oddi (see Fig. 46–1), thereby worsening the disease course. However, meperidine is not recommended as a first-line agent because of the risk of adverse effects and dosing limitations. As a result many hospitals have either restricted or eliminated the use of meperidine. Active metabolites of meperidine accumulate with kidney dysfunction and may cause seizures or psychosis. The maximum recommended parenteral dose of meperidine is 600 mg/day in divided doses in patients with normal kidney function, but it should not be used in patients with kidney dysfunction.

Parenteral morphine is often recommended for pain control because it provides a longer duration of pain relief than meperidine with less risk of seizures. However, its use in acute pancreatitis is sometimes avoided because it is thought to cause spasm of the sphincter of Oddi, increases in serum amylase, and, rarely, pancreatitis. Although morphine increases biliary pressure, there is no evidence to indicate that it is contraindicated for use in acute pancreatitis as no studies have compared clinical outcomes of acute pancreatitis using various analgesics. Hydromorphone may be used because it also has a longer half-life than meperidine. Patient-controlled analgesia should be considered in patients who require frequent opioid dosing (e.g., every 2 to 3 hours). Dosing of pain medications should be monitored carefully and adjusted daily. There is no evidence that antisecretory agents, such as histamine $\text{H}_2$-receptor antagonists or proton pump inhibitors, prevent an exacerbation of abdominal pain.

**Prevention of Infection**

Prophylactic antibiotics do not offer any benefit in cases of mild acute pancreatitis or when there is no necrosis. Use of antibiotics in patients with severe acute pancreatic necrosis, but without infection, is not currently supported by randomized, controlled trials. This is true with or without the presence of pancreatic necrosis.

**Nutrition**

Intensive care is required when there is no necrosis. Use of antibiotics in patients with severe acute necrotizing pancreatitis is sometimes avoided because of the risk of adverse effects and dosing limitations. As a result many hospitals have either restricted or eliminated the use of meperidine.

Some clinicians believe that antibiotic prophylaxis is necessary in patients with severe acute pancreatitis in order to prevent pancreatic infection, whereas others believe that this practice is unnecessary. Antibiotic use in acute pancreatitis remains controversial, especially in patients with definite proof of pancreatic necrosis.

CHRONIC PANCREATITIS

Chronic pancreatitis results from long-standing pancreatic inflammation resulting in irreversible destruction of pancreatic tissue with fibrin deposition, leading to a loss of exocrine and endocrine function. It has four different stages, beginning with a preclinical inflammatory stage in which patients remain asymptomatic or have indistinguishable symptoms. In the second stage patients present with acute attacks that often resemble those of acute pancreatitis. However, some benefit has been demonstrated with somatostatin, diclofenac suppositories, and gabexate. To date, there have not been any studies to evaluate the cost-effectiveness of prophylactic therapy.

ETIOLOGY

Chronic alcohol consumption, especially heavy drinking, remains the leading cause of chronic pancreatitis in Western society, accounting for approximately 70% to 80% of cases. Generally, consumption of 100 to 150 g/day of alcohol over 10 to 15 years poses a significant risk of chronic pancreatitis. Twenty percent of the remaining cases can be classified as idiopathic, while 10% are due to rare causes, such as autoimmune, hereditary, and tropical pancreatitis. Various genetic alterations have also been associated with the occurrence of chronic pancreatitis, including mutations of the

**PATHOPHYSIOLOGY**

Although the exact mechanism for the pathogenesis of chronic pancreatitis is unknown several theories have been proposed. The oxidative stress theory proposes that the pancreas is exposed to by-products of mixed-function oxidases that lead to an inflammatory reaction. Increased activity of hepatic and pancreatic oxidases may be due to increased exposure to substrates (e.g., fat), inducers (e.g., alcohol), or other substances. A comparison of serum oxidative markers in chronic pancreatitis patients versus healthy volunteers supports this theory. A toxic-metabolic theory focuses on alcohol as a primary causative agent where by-products of its metabolism in the pancreas lead to lipid accumulation in acinar cells and eventual fatty degeneration of the pancreas. Ductal obstruction theories state that alcohol leads to obstruction of pancreatic ducts secondary to increased protein deposition and stone formation. This leads to scarring of ductal epithelial cells, which potentiates further obstruction and eventually results in acinar atrophy and fibrin deposition. The final major theory suggests that periductal necrosis from repeated episodes of acute pancreatitis eventually leads to ductal obstruction and stone formation with subsequent acinar atrophy and fibrosis.

Regardless of the pathophysiologic mechanism several pieces of evidence now point to activation of pancreatic stellate cells as the cause of fibrin deposition in chronic pancreatitis. Various toxins, oxidative stress, and inflammatory mediators have been shown to activate pancreatic stellate cells. Cellular signaling pathways involved in this activation are modulated by hydroxymethylglutaryl-coenzyme A reductases and peroxisome proliferator-activated receptor-gamma nuclear receptors. As an example, exposure of the pancreas to alcohol and its metabolites leads to the production of various mediators and proinflammatory cytokines, especially tumor necrosis factor alpha and interleukins 1 and 6. These then activate pancreatic stellate cells, which initiate fibrinogenesis. Other mediators generated by the stellate cells themselves perpetuate continued stellate cell activation.

The pathogenesis of pain in chronic pancreatitis has long been thought to be the result of increased pancreatic parenchymal pressure from obstruction, inflammation, and necrosis. A neurogenic mechanism may also be responsible. Continued activation of trypsin not only damages afferent neurons but also has effects on sensory pain receptors within the pancreas. Changes also occur within the central nervous system that further contribute to the neurogenic mechanism of pain. Therefore, compression of pancreatic nerve fibers after a meal along with continuous firing of peripheral and central neurons may explain the burning and shooting pain of chronic pancreatitis.

**CLINICAL PRESENTATION**

Chronic pain, malabsorption with resultant steatorrhea, and diabetes mellitus are the hallmark complications and symptoms of chronic pancreatitis. Although abdominal pain is the most common symptom at any stage, patients may present with various signs and symptoms depending on the stage of the disease. A more comprehensive list of the common signs and symptoms is presented in Table 46–7.

**Diagnosis**

The diagnosis of chronic pancreatitis is based primarily on presenting signs and symptoms in combination with either imaging or pancreatic function studies (see Table 46–7). Although histology would be the best diagnostic test it is difficult and risky to perform and is generally not recommended. Therefore, testing usually begins with noninvasive and inexpensive studies such as serum trypsinogen, fecal elastase, mixed triglyceride breath test, and abdominal ultrasonography. However, these tests are usually useful only in advanced disease. Magnetic resonance cholangiopancreatography or CT may be used next. The most sensitive studies are the secretin and CCK stimulation tests for exocrine pancreatic insufficiency. Performing these studies is uncomfortable for patients and they are not widely available, so they are usually reserved to rule out chronic pancreatitis if imaging studies are nondiagnostic. The gold standard invasive study is ERCP. However, due to the risks associated with this procedure endoscopic ultrasonography (EUS) has become an accepted alternative for the diagnosis of chronic pancreatitis.

**Clinical Course and Prognosis**

The clinical course of chronic pancreatitis depends upon the etiology. The median age at onset is as early as 10 years for hereditary chronic pancreatitis, whereas alcoholic and late-onset idiopathic chronic pancreatitis have median onsets of 36 and 62 years, respectively. Exocrine insufficiency, which occurs when lipase secretion is less than 10% of normal, develops about 5 years after diagnosis in alcoholic chronic pancreatitis and 22 years in hereditary chronic pancreatitis. Diabetes mellitus was shown to occur about 8 years after diagnosis of alcoholic chronic pancreatitis and up to 27 years after diagnosis of early-onset idiopathic chronic.
pancreatitis. Resolution of pain from pancreatic burnout tended to coincide with exocrine insufficiency.

The life expectancy of patients with chronic pancreatitis is shorter than that of the general population. The 10-year survival is 70%, while the 20-year rate was 45%. However, death in patients with chronic pancreatitis most commonly results from cardiovascular disease, infection, or malignancy rather than from the disease itself. One of the most significant complications of long-standing disease is pancreatic cancer. Patients with alcoholic chronic pancreatitis are 15 times as likely as the general population to develop pancreatic cancer, while 40% of those with hereditary chronic pancreatitis may be diagnosed.

**Laboratory studies**

- CBC to rule out infection (i.e., infected pseudocyst)
- Serum amylase and lipase
- Low specificity for chronic pancreatitis
- May be elevated in acute exacerbations
- Usually are normal or only slightly elevated
- Total bilirubin, alkaline phosphatase, and hepatic transaminases may be elevated with ductal obstruction
- Fasting serum glucose
- Pancreatic function tests
  - Serum trypsinogen (<20 ng/mL is abnormal)
  - Fecal elastase (<200 mcg/g of stool is abnormal)
  - Fecal fat estimation (>7 g/day is abnormal; need to collect 72 hours of stool)
- Secretin stimulation (evaluates duodenal bicarbonate secretion)
- 
- 13C-mixed triglyceride breath test
- Serum albumin (may be low with malnutrition)
- Serum calcium (may be low with malnutrition)

**Imaging studies**

- Noninvasive
  - Abdominal ultrasound
  - Magnetic resonance cholangiopancreatography (MRCP)
- Invasive
  - Endoscopic ultrasonography (EUS)
  - Endoscopic retrograde cholangiopancreatography (ERCP)

**TREATMENT**

### Chronic Pancreatitis

#### DESIRED OUTCOME

The major goals in the treatment of uncomplicated chronic pancreatitis are relief of abdominal pain, treatment of the associated complications of malabsorption and diabetes mellitus, and improvement in quality of life. Secondary goals include treating associated disorders such as depression and malnutrition.

#### GENERAL APPROACH TO TREATMENT

Treatment of chronic pancreatitis and its complications involves various nonpharmacologic and pharmacologic interventions. Lifestyle modifications should include abstinence from alcohol and smoking cessation. Also, patients with steatorrhea may need to eat smaller, more frequent meals and reduce dietary fat intake. The majority of patients require analgesics and pancreatic enzyme supplementation. Pain can initially be controlled with medications but may require more aggressive medical and surgical therapies as the disease progresses. Patients with malabsorption require pancreatic enzymes to reduce steatorrhea and maintain adequate nutrient absorption. An antisecretory agent may be added to the regimen when enzymes alone provide an inadequate reduction in steatorrhea.

#### NONPHARMACOLOGIC THERAPY

In addition to medical management the treatment of chronic pancreatitis includes both lifestyle and dietary modifications. Patients should be counseled to abstain from alcohol use, and smoking cessation should be advocated. It is unclear if cessation of alcohol use reduces pain in patients with alcoholic chronic pancreatitis, but its use hastens disease progression. Patients with steatorrhea should be counseled to eat small and frequent meals. A reduction in dietary fat is not needed empirically, but a decrease to 0.5 g/kg/day is recommended for those whose symptoms are uncontrolled with enzyme supplementation. Patients who do not consume adequate calories from their normal diet may be given whole protein or peptide-based oral nutritional supplements. Supplementation with medium-chain triglycerides, which do not require lipolysis, should be considered for patients with steatorrhea who are unable to gain weight. Complete enteral nutrition is recommended for patients who cannot consume adequate calories, have continued weight loss, experience complications, or require surgery. A jejunal feeding tube is the recommended route for administration of enteral nutrition in chronic pancreatitis patients; it increases patient weight and decreases abdominal pain and opioid use.

Invasive procedures and surgery are primarily used to treat uncontrolled pain and the associated complications of chronic pancreatitis. Stents placed via ERCP may be used to treat pancreatic duct strictures in order to relieve parenchymal pressure and reduce pain. Extracorporeal shock wave lithotripsy can be used to break up pancreatic stones with ultrasonic vibration prior to removal by ERCP. Some complications of chronic pancreatitis that can be treated endoscopically include common bile duct strictures, duodenal obstructions, and pancreatic pseudocysts. Various surgical techniques, including total pancreatectomy, may also be used to relieve pain associated with chronic pancreatitis. Surgery is more effective at relieving pain compared with endoscopic procedures, but these trials have a number of limitations.

CBC, complete blood count.

Data from references 4, 5, 129.
Finally, total pancreatectomy with transplantation of pancreatic islet cells to reduce the need for exogenous insulin is a possible option for the treatment of pain due to chronic pancreatitis. \(^82,110\)

PHARMACOLOGIC THERAPY

General Recommendations

Pharmacologic therapy of chronic pancreatitis is aimed at controlling pain, treating malabsorption and associated steatorrhea, and controlling diabetes mellitus. Once other causes have been excluded nonopioid analgesics should be tried initially for pain management (Fig. 46–4). \(^4,5\) Patients unresponsive to nonopioid analgesics may be given a trial of pancreatic enzyme supplements prior to addition of opioids. \(^4,82,95\) If these measures fail, an oral opioid should be added to the drug regimen. Opioids administered by nonoral routes should be reserved for patients who cannot take oral medications or whose pain is unresponsive to oral opioids. Additional agents may be considered for added pain control and disorders associated with chronic pancreatitis.

Most patients with malabsorption will require a modification in diet along with pancreatic enzyme supplementation in order to achieve adequate nutritional status and reduction in steatorrhea (Fig. 46–5). An antisecretory agent should be added to the regimen when there is an inadequate response to enzyme therapy alone. \(^3\) If these measures are ineffective, documentation of the diagnosis and exclusion of other diseases should be undertaken. Exogenous insulin is the primary pharmacologic agent used in the treatment of diabetes mellitus associated with chronic pancreatitis. \(^4\) However, some patients may have favorable results with the use of oral agents for control of blood glucose.

Relief of Chronic Abdominal Pain

Analgesics Pain from chronic pancreatitis can initially be treated with nonopioid analgesics, but opioids will eventually be required as the disease progresses. \(^7\) Therapy should begin with acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) (Table 46–8). \(^4,5\) Regimens should be individualized and should begin with the lowest effective dose. The dosage regimen should be maximized before adding or substituting agents. Analgesics should be scheduled around the clock rather than as needed in order to maximize efficacy. Also, scheduling analgesics prior to meals should help decrease postprandial pain. When nonopioid analgesics fail to control pain low-potency opioids (e.g., hydrocodone) should be added to the regimen (see Table 46–8). Tramadol has also been used successfully to treat pain in patients with chronic pancreatitis, but at a higher dose than that approved in the United States. \(^4\) Severe pain unresponsive to these therapies necessitates the use of opiate analgesics. Although opioids carry about a 10% to 30% risk of addiction in this population their use should not be withheld. \(^4\) Unless contraindicated, oral opioids should be used before parenteral, transdermal, or other dosage forms. Although oxycodone was found to relieve pain better than morphine in a study of simulated chronic pancreatitis pain, adequate trials comparing agents have not been conducted. \(^111\) Therefore, the choice of agent should be based on cost, compliance, and avoidance of adverse drug events (e.g., allergic reactions).

CLINICAL CONTROVERSY

Since the evidence supporting the use of pancreatic enzyme supplements for treating pain associated with chronic pancreatitis is not overwhelming, clinicians debate over their use for this purpose. Often the decision to use enzyme supplements for the treatment of pain comes from clinical experience and the knowledge that their use carries minimal risk of adverse effects.
In many cases the lipase dose will need to be increased to administer an enteric-coated product with an antisecretory agent in order to increase the amount of proteases available in the duodenum (see Table 46–8). No studies have been conducted using such a regimen for the treatment of pain from chronic pancreatitis.

### Other Agents
Various adjunctive agents are also used in patients experiencing pain from chronic pancreatitis. Selective serotonin reuptake inhibitors and tricyclic antidepressants are used both for treating the concomitant depression that often occurs in patients with chronic pancreatitis and for their potential effects on pain (see Table 46–8). Gabapentin has also been used as an adjunct to opioids. Little evidence supports these therapies, but their use in this patient population is not uncommon. Oxytetracycline and allopurinol have also been studied for the treatment of chronic pancreatitis pain, but the evidence does not support their use. There is evidence showing that patients with chronic pancreatitis have increased oxidative stress, and the use of antioxidants, such as selenium, vitamins C and E, and beta-carotene, has demonstrated some benefit in relieving pain and improving quality of life in these patients.

### Treatment of Malabsorption
Pancreatic enzyme supplementation and reduction in dietary fat intake are the primary treatments for malabsorption due to chronic pancreatitis. Treatment should begin when steatorrhea is documented and persistent weight loss occurs despite initial dietary modifications. The combination of pancreatic enzymes and a reduction in dietary fat enhances the patient’s nutritional status and reduces steatorrhea. Malabsorption is minimized if the concentration of lipase delivered to the duodenum with supplementation is about 10% of normal pancreatic output. This requires that 25,000 to 40,000 units of lipase be administered with each meal (see Table 46–8).

In many cases the lipase dose will need to be increased due to insufficient lipolytic activity, but doses greater than 75,000 units per meal are not recommended. There is little evidence regarding the optimal dosage form and administration of pancreatic enzyme supplements. Most studies have compared them to placebo rather than to other enzyme products and have used quantitation of fat absorption or elimination rather than weight gain as a primary measure of efficacy. Although they improve fat absorption, they may not completely eliminate steatorrhea. However, they improve the quality of life of patients with chronic pancreatitis. Since most exogenous lipase is rapidly and irreversibly destroyed at low intragastric pH, enteric-coated products are preferred for the treatment of malabsorption and steatorrhea. The enteric coating dissolves at a pH greater than 5.5, which allows a sufficient quantity of enzymes to remain intact until dissolution of the coating in the duodenum. Treatment should begin when steatorrhea is documented and persistent weight loss occurs despite initial dietary modifications. The combination of pancreatic enzymes and a reduction in dietary fat enhances the patient’s nutritional status and reduces steatorrhea. Malabsorption is minimized if the concentration of lipase delivered to the duodenum with supplementation is about 10% of normal pancreatic output. This requires that 25,000 to 40,000 units of lipase be administered with each meal (see Table 46–8). In many cases the lipase dose will need to be increased due to insufficient lipolytic activity, but doses greater than 75,000 units per meal are not recommended.

There is little evidence regarding the optimal dosage form and administration of pancreatic enzyme supplements. Most studies have compared them to placebo rather than to other enzyme products and have used quantitation of fat absorption or elimination rather than weight gain as a primary measure of efficacy. Although they improve fat absorption, they may not completely eliminate steatorrhea. However, they improve the quality of life of patients with chronic pancreatitis.

### Pancreatic Enzymes
Although pancreatic enzymes are primarily used to treat malabsorption associated with chronic pancreatitis they are also used to treat pain from the disease. Relief of pain using pancreatic enzymes is thought to be due to their ability to break down CCK. Normally, the release of CCK, which causes an increase in pancreatic secretion, is inhibited by trypsin. However, there is a decrease in the production of trypsin in patients with chronic pancreatitis. This leads to a loss of negative feedback on the release of CCK and thus an increase in pain due to unabated pancreatic secretion. The proteases in pancreatic enzyme supplements are thought to act as substitutes for endogenous trypsin, leading to a decrease in CCK release.

Despite this intuitive mechanism there were mixed results from trials investigating pancreatic enzyme supplements for the treatment of pain from chronic pancreatitis. This may be due to the differences between the various enzyme formulations used in the trials as well as the small number of subjects enrolled. A meta-analysis that pooled the results of all six prospective trials found no benefit with the use of enzyme supplements for pain relief. However, the two trials that used non-enteric-coated enzyme formulations demonstrated a benefit in the treatment of pain. Enteric-coated formulations may not release enough proteases in the duodenum to inhibit CCK release. However, non-enteric-coated products are no longer available in the United States. Therefore, it may be reasonable to administer an enteric-coated product with an antisecretory agent in order to increase the amount of proteases available in the duodenum (see Table 46–8). No studies have been conducted using such a regimen for the treatment of pain from chronic pancreatitis.
Pancreatic Enzyme Supplements  Until recently none of the commercially available pancreatic enzyme supplements were approved by the FDA because they predated enactment of the Food, Drug, and Cosmetic Act of 1938. Since the FDA announced in 2004 that all products would have to seek approval only one has been approved and three others have submitted new drug applications. Dosage forms of products currently available in the United States include enteric-coated microspheres, bicarbonate-buffered microspheres, enteric-coated minispheres, and enteric-coated minitablets encased in a cellulose or gelatin capsule (Table 46-9). Enzymes are easily administered to patients able to swallow the capsules or their contents. However, administration to patients with enteral feeding tubes presents a challenge. Products containing microspheres may be administered through feeding tubes in an applesauce or apple juice mixture. Clinicians must be aware, however, that available products are not equivalent and should consider this before substituting products in patients who require administration through a nonoral route.

Adverse reactions from pancreatic enzyme supplements are generally benign. High doses can lead to nausea, diarrhea, and intestinal upset. One of the more serious adverse effects of these products is fibrosing colonopathy. It occurs when the enzymes cause deposition of fibrin in the colon, leading to colonic stricture. This reaction is uncommon and has been reported mostly in children with cystic fibrosis who received high doses of enzymes for prolonged periods. Certain enteric coatings may specifically invoke this reaction. Another concern with pancreatic enzymes is the risk of possible viral infection due to contamination of these porcine-derived products. Finally, pancreatic enzymes have been associated with deficiencies in fat-soluble vitamins, and appropriate monitoring and supplementation, especially of vitamin D, should be instituted. Adjuncts to Enzyme Therapy  The addition of a histamine- receptor antagonist or proton pump inhibitor to pancreatic enzyme supplementation may increase the effectiveness of enzyme therapy for malabsorption and steatorrhea. The beneficial effects of these agents result from an increase in gastric and duodenal pH. This is thought to result in an increase in the amount of active enzymes available in the duodenum. Traditionally, their use has been advocated with non-enteric-coated enzyme products. However, their use in combination with enteric-coated preparations results in similar efficacy between standard and low-dose enzyme regimens.

PHARMACOECONOMIC CONSIDERATIONS  The pharmacoeconomic issues associated with the medical treatment of acute pancreatitis and chronic pancreatitis have not been extensively examined. Aggressive medical and surgical care decreases mortality in acute pancreatitis, but the overall cost-effectiveness of a specific treatment is unknown. The relief of abdominal pain in acute pancreatitis and chronic pancreatitis, as well as pancreatic enzyme supplementation in patients with chronic pancreatitis, improves quality of life and nutritional status.

With so few FDA-approved pancreatic enzyme supplements currently available pricing should remain fairly competitive. However, if cost is based on the total number of capsules per day, rather than the cost of a single capsule, high-potency preparations may help minimize cost. The addition of a histamine- receptor antagonist or proton pump inhibitor may actually be cost-effective for patients with chronic pancreatitis who are inadequately controlled on maximal enzyme therapy. They reduce the amount of enzymes needed and they may improve efficacy.

EVALUATION OF THERAPEUTIC OUTCOMES  ACUTE PANCREATITIS  Hydration status, serum electrolytes, pain control, and nutritional status should be assessed periodically in patients with mild acute pancreatitis, depending on the degree of abdominal pain and fluid loss. Patients with severe acute pancreatitis should receive intensive care and close monitoring of vital signs, fluid and electrolyte status, white blood cell count, blood glucose, lactate dehydrogenase, aspartate aminotransferase, serum albumin, hematocrit, blood urea nitrogen, serum creatinine, and international normalized ratio. Continuous hemodynamic and arterial blood gas monitoring is essential. Serum lipase, amylase, and bilirubin require less frequent monitoring. The patient should also be monitored for signs of infection, relief of abdominal pain, and adequate nutritional status. Severity of disease and patient response should be assessed using an evidence-based method, for example APACHE II.

CHRONIC PANCREATITIS  The severity and frequency of abdominal pain should be assessed periodically in patients with chronic pancreatitis using a standardized scale to determine the efficacy of pain therapy. Patients receiving opioids should be prescribed scheduled bowel regimens and be monitored for constipation. Patients receiving pancreatic enzymes for malabsorption should have their weight and stool frequency and consistency monitored periodically. More objective assessments of fecal fat content, such as the 4C-mixed triglyceride breath test, can be utilized but are usually unnecessary and impractical in general clinical practice. Blood glucose must be closely monitored in patients with diabetes mellitus, and those with long-standing disease should receive appropriate monitoring for nephropathy, retinopathy, and neuropathy.

ACKNOWLEDGMENT  The authors wish to acknowledge the contributions of Rosemary R. Berardi, Pharm.D., FCCP, FASHP, to previous editions of this chapter.
REFERENCES

Hepatitis A is transmitted via the fecal–oral route. Transmission is most likely to occur through travel to countries with high rates of hepatitis A, poor sanitation and hygiene, and overcrowded areas.

Hepatitis A causes an acute, self-limiting illness and does not lead to chronic infection. There are three stages of infection: incubation, acute hepatitis, and convalescence. Rarely, the infection progresses to liver failure.

Treatment of hepatitis A consists of supportive care. There is no role for antiviral agents in treatment.

Hepatitis B causes both acute and chronic infection. Infants and children are at high risk for chronic infection.

Several therapies are available for hepatitis B, including lamivudine, interferon α2b, pegylated interferon α2a, entecavir, adefovir, telbivudine, and tenofovir. Patient status, extent of disease, viral load, and viral resistance are all considered when deciding on treatment.

Chronic hepatitis B patients may require long-term therapy. Long-term therapy poses a challenge because of the potential for developing resistance. Resistance to lamivudine and telbivudine is most common, although resistance mutations to adefovir and entecavir have also been seen. Optimal treatment of resistant strains is unknown.

Prevention of hepatitis B infections focuses on immunization of all children and at-risk adults.

Hepatitis C is an insidious, blood-borne infection. Injection drug use is the major mode of transmission in the United States.

Combination pegylated interferon and ribavirin therapy is the treatment of choice for hepatitis C. Treatment duration for hepatitis C infections is 48 weeks for viral genotype 1, and 24 weeks for genotypes 2 and 3. However, therapy may be optimized based on infecting genotype and virologic response. Viral genotype 1 is most difficult to treat.

Side effects of hepatitis C therapy pose a significant obstacle to completion of therapy and chance for cure. Adjunct pharmacologic therapy and dose reductions may be necessary to prevent premature cessation of treatment.

The major hepatotropic viruses responsible for viral hepatitis are hepatitis A, hepatitis B, hepatitis C, delta hepatitis, and hepatitis E. All share clinical, biochemical, immunoserologic, and histologic findings. Both hepatitis A and E are spread through fecal–oral contamination; whereas hepatitis B, C, and delta are transmitted parenterally. Infection with delta hepatitis requires coinfection with hepatitis B. Although the rates of acute infection have declined, viral hepatitis remains a major cause of morbidity and mortality with a significant impact on healthcare costs in the United States. Significant therapeutic advances have occurred with hepatitis B with the approval of new agents and updated guidelines for care. For hepatitis C, the challenge remains of increasing successful outcomes while minimizing side effects of therapy. This chapter focuses on hepatitides A, B, and C.

Hepatitis A virus (HAV), or infectious hepatitis, is often a self-limiting and acute viral infection of the liver posing a health risk worldwide. The infection is rarely fatal. According to the Centers for Disease Control and Prevention (CDC), the 2,979 reported cases of acute clinical hepatitis A infection in the United States in 2007 were the lowest in recorded history. Although vaccine preventable, HAV continues to be one of the most commonly reported infections.

Epidemiology

Various patient groups are at increased risk for infection with HAV. Children pose a particular problem with the spread of the disease because they often remain clinically asymptomatic and are infectious for longer periods of time than adults. Traditionally, the most likely patient group affected is household or close personal contacts of an infected person. Infection primarily occurs through the fecal–oral route, by person-to-person, or by ingestion of contaminated food or water. Incidentally, HAV’s prevalence is linked to regions with low socioeconomic status and specifically to those with poor sanitary conditions and overcrowding. Rarely, the virus can be spread through blood or blood products. Despite being detectable in saliva, there are no data to suggest transmission through this mode of contact. International travel and immigration also mitigate potential exposure to the virus.

International travel, in particular travel to HAV endemic areas, continues to be a major risk factor for HAV infection. Although rates have declined as a result of successful vaccination programs to a record low of 1.0 cases per 100,000 people in 2007, the proportion...
of HAV rates among international travelers continues to rise. Other identified risk factors include sexual and household contact with a HAV infected person, men who have sex with men (MSM), and injection drug users (IDUs). Additional patient groups that are at risk include patients with chronic liver disease and persons working with nonhuman primates. For half of all identified HAV cases in 2007, no risk factor was identified. In pregnant women, acute HAV infection may be associated with maternal complications and preterm labor. Food-borne outbreaks also occur; a 2003 outbreak in Pennsylvania was associated with more than 500 persons infected and 3 deaths, and was linked to green onions imported from Mexico.

HAV infections acquired through international travel create significant HAV-associated costs in terms of loss of work time and healthcare costs. Despite low endemic rates and successful vaccinations of at-risk populations in the United States, unvaccinated children acquiring HAV infections abroad can serve as reservoirs of the virus upon return to the United States, even while remaining clinically asymptomatic themselves. Nearly 40% of children younger than age 15 years with HAV had international travel as a risk factor in 2004. According to the CDC, the majority of travel-related cases correspond to travel to Central and South America and Mexico. Most Americans traveling to Mexico do not consider that country to be a risk in part because of Mexico’s proximity to the United States. Moreover, most tourists falsely believe that higher-end resorts imply safety and that short visits to foreign countries are not associated with a risk for infection. In fact, frequent, short visits will have a cumulative risk for infection that should not be ignored.

ETIOLOGY

Hepatitis A is a RNA virus belonging to the genus Hepatovirus of the Picornaviridae family. Humans are the only known reservoir for the virus and transmission occurs primarily through the fecal–oral route. The virus is stable in the environment for at least a month and requires heating foods to a minimum of 85°C (185°F) for 1 minute or disinfecting with a 1:100 dilution of sodium hypochlorite (bleach) in tap water for inactivation. Multiple genotypes of the virus exist and although the clinical implications of infection by particular type are unknown, types I and III are the most commonly identified in human outbreaks.

PATHOPHYSIOLOGY

HAV infection is usually acute, self-limiting, and confers lifelong immunity. HAV’s life cycle in the human host classically begins with ingestion of the virus. Absorption in the stomach or small intestine allows entry into the circulation and uptake by the liver. Replication of the virus occurs within hepatocytes and gastrointestinal epithelial cells. New virus particles are released into the blood and secreted into bile by the liver. The virus is then either reabsorbed to continue its cycle or excreted in the stool. The enterohepatic cycle will continue until interrupted by antibody reabsorption. The exact mechanism of replication and secretion is unknown; however, the initial viral expansion does not seem to be associated with hepatic injury as peak viral fecal excretion precedes clinical signs and symptoms of infection.

On biopsy, acute hepatitis is marked by hepatocellular degeneration, inflammatory infiltrate, and hepatocyte regeneration. Hepatocellular degeneration occurs as a result of immune-mediated injury and not as a direct cytopathic effect of the virus. Clinical symptoms of HAV typically identify the onset of the immune response. Cytolytic T cells mediate hepatocyte lysis to eradicate the virus and mark the cellular immune response with rising hepatic enzyme levels.

CLINICAL PRESENTATION

The incubation period of HAV is approximately 28 days, with a range of 15 to 50 days. Viremia occurs within 1 to 2 weeks of exposure as patients begin to shed the virus. Table 47–1 summarizes the clinical features of acute hepatitis A. Peak fecal shedding of the virus precedes the onset of clinical symptoms and elevated liver enzymes. Acute hepatitis follows, beginning with the preicteric or prodromal period. The phase is marked by an abrupt onset of nonspecific symptoms, some very mild. Other, more unusual symptoms include chills, myalgia, arthralgia, cough, constipation, diarrhea, pruritus, and urticaria. The phase generally lasts 2 months. There are no specific symptoms unique to HAV. Liver enzyme levels rise within the first weeks of infection, peaking approximately in the fourth week and normalizing by the eighth week. Conjugated bilirubinemia, or dark urine, precedes the onset of the icteric period. The concentration of virus declines at this point and patients are generally considered noninfectious approximately 1 week after the onset of jaundice. Gastrointestinal (GI) symptoms may persist or subside during this time and some patients may have hepatomegaly. Duration of the icteric period varies and corresponds to disease duration. It averages between 7 and 30 days.

Symptoms and severity of HAV vary according to age. Children younger than 6 years of age typically are asymptomatic. Symptoms, if they do occur, do not include jaundice. In older children and adults, the majority of patients present with symptoms that last less than 2 months and 70% of adults experience jaundice. Peak viral shedding precedes the onset of GI symptoms in adults. In young children, shedding can occur for months following diagnosis. Because children are often asymptomatic and will shed the virus for long periods of time they can serve as a reservoir for the spread of HAV.

HAV RNA is detectable in the serum for an average of 17 days before peak alanine aminotransferase (ALT) levels and can persist for an average of 79 days after the onset of symptoms. In some patients, serum HAV is detectable for more than a year. Immunoglobulin (Ig) M antibody to HAV (anti-HAV) is required for a diagnosis of acute infection. Serum HAV becomes detectable to 10 days before the onset of symptoms and can persist for months. IgG anti-HAV replaces IgM and indicates host immunity following the acute phase of the infection. Serologic tests exist but should be interpreted with caution. FDA-approved assays for serologic testing detect IgM and total anti-HAV (IgG and IgM). Patients who have detectable total anti-HAV and a negative IgM have resolved
their infection. Although patients who are successfully immunized will have IgG, assays are not sensitive enough to detect anti-HAV in most patients. Similarly, patients who receive intramuscular (IM) Ig will also have anti-HAV but concentrations are below the level of detection of most assays.\(^2,^3\) Concentrations of antibody often fall to 10 to 100 times lower than what would be expected after a natural course of infection. Although a positive anti-HAV result confirms protection, undetectable concentration of anti-HAV may not necessarily imply that protective levels were not achieved.\(^4\)

HAV does not lead to chronic infections. Some patients may experience symptoms for up to 9 months. Rarely, patients experience complications from HAV, including relapsing hepatitis, cholestatic hepatitis, and fulminant hepatitis. Fatalities from HAV are generally rare though more likely in patients older than age 50 years and in persons with preexisting liver disease.\(^5\) Fulminant hepatitis occurs mostly in young children and adults with chronic liver disease. Although occurring in 0.01% of clinical infections, fulminant hepatitis has a high fatality rate and therapy consists of supportive care.\(^6\)

### Diagnosis

A diagnosis of HAV is based on clinical criteria of an acute onset of fatigue, abdominal pain, loss of appetite, intermittent nausea and vomiting, jaundice or elevated serum aminotransferase levels, and serologic testing for IgM anti-HAV. Serologic testing is necessary to differentiate the diagnosis from other types of hepatitis.

### Treatment

#### Hepatitis A Virus

##### DESIRED OUTCOME

- The majority of people infected with HAV can be expected to fully recover without clinical sequelae.\(^7\) Nearly all individuals will have clinical resolution within 6 months of the infection, and a majority will have done so by 2 months. Rarely, symptoms persist for longer or patients relapse. The ultimate goal of therapy is complete clinical resolution. Other goals include reducing complications from the infection, normalization of liver function, and reducing infectivity and transmission.

##### GENERAL APPROACH TO TREATMENT

No specific treatment options exist for HAV infections. Instead, patients should receive general supportive care. In patients who develop liver failure, transplant is the only option. Although hepatocellular damage occurs through immune-mediated responses, steroid use is not recommended.\(^8\) Prevention and prophylaxis are key to managing the virus. The importance of good hand hygiene cannot be overemphasized in preventing disease transmission. Immunoglobulin is used for pre- and postexposure prophylaxis, and offers passive immunity. Active immunity is achieved through vaccination. Vaccines were approved for use in 1995 and implemented in the routine vaccination of children, as well as at-risk adults, to reduce the overall incidence of HAV.\(^9\)

Prevaccination serologic testing to determine susceptibility is generally not recommended. In some cases, testing may be cost effective if the cost of the test is less than that of the vaccine and if the person is from a moderate to high endemic area and likely to have prior immunity. Prevaccination serologic testing of children is not recommended. Similarly, because of high vaccine response, postvaccine serologic testing is not recommended.\(^9\)

### Prevention of Hepatitis A

HAV is easily preventable with vaccination. Because children often serve as reservoirs of the disease, vaccine programs have targeted children as the most effective means to control HAV. Two vaccines for HAV are available and are incorporated into the routine childhood vaccination schedule. In October 2005, the FDA reduced the minimum age for the vaccines to 12 months of age. In response, the Advisory Committee on Immunization Practices recommended expanding vaccine coverage to all children, including catch-up programs for children living in areas without existing vaccination programs. The new recommendations were enacted in the attempt to further reduce HAV incidence rates and possibly to eradicate the virus.\(^10\) In 2007, the U.S. Department of Health and Human Services issued a health advisory after receiving reports of HAV from international adoptees. Guidelines for international adoptees and their adoptive parents are available from the CDC. Adult vaccination recommendations also exist (Table 47–2).

Routine prevention of HAV transmission includes regular hand washing with soap and water after using the bathroom, changing a diaper, and before food preparation. For travelers to countries with high endemic rates of HAV, even short-term stays in urban and upscale resorts are not risk free.\(^4\) In particular, contaminated water and ice, fresh produce, and any uncooked foods pose a risk.\(^7\)

#### Vaccines to Prevent Hepatitis A

Two inactivated virus vaccines are currently licensed in the United States: Havrix and Vaqta. Both vaccines are inactivated virus and are available for pediatric and adult use. The differences in the two vaccines are in the use of a preservative and in expression of antigen content. Vaqta is formulated without a preservative and uses units of HAV antigen to express potency. Havrix uses 2-phenoxypenol as a preservative and antigen content is expressed as enzyme-linked immunosorbent assay units. Pediatric dosing is indicated for children 12 months of age through 18 years of age, and adult dosing is for patients ages 19 years and older (Table 47–3).\(^5\) Although high seroconversion rates of 294% are achieved with the first dose, both vaccines recommend a booster shot to achieve the highest possible antibody titers. In situations of postexposure prophylaxis, previously only immunoglobulin was indicated but recent guidelines changes allow the use of vaccines for this indication. The change to the use of the vaccine is advantageous as vaccination confers the benefit of long-term immunity against HAV.\(^11\) Both vaccines may be given concomitantly with immunoglobulin and the two brands are interchangeable for booster shots.\(^8\)

*Travelers to Canada, Western Europe, Japan, Australia, or New Zealand are at no greater risk for infection than they are in the United States. All other travelers should be assessed for HAV risk. From Centers for Disease Control and Prevention.\(^4,^7\)*
Vaccine efficacy may be reduced in certain patient populations. In HIV (human immunodeficiency virus)-infected patients, greater immunogenic response may correlate with higher baseline CD4 cell counts. Response to the HAV vaccine as determined by detection of anti-HAV after vaccination found that among HIV patients, females and patients with CD4 counts >200 cells/mm³ at vaccination had a higher response rate.16

The most common side effects of the vaccines include soreness and warmth at the injection site, headache, malaise, and pain. Reported serious adverse events include anaphylaxis, Guillain-Barré syndrome, brachial plexus neuropathy, transverse myelitis, multiple sclerosis, encephalopathy, and erythema multiforme. However, causality of these reported events has not been established. Furthermore, incidence of serious adverse events in the vaccinated population did not differ from the incidence in nonvaccinated populations. It is important to note that more than 65 million doses of the vaccine have been administered and despite routine monitoring for adverse events, there are no data to suggest a greater incidence of serious adverse events among vaccinated people compared with nonvaccinated. The vaccine is considered safe.8

Twinrix is a bivalent vaccine for hepatitides A and B that was approved by the FDA in 2001. The vaccine is approved for people ages 18 and older and is given at 0, 1, and 6 months. Although seroconversion exceeds 90% for HAV after the first dose, the full three-dose series is required for maximal hepatitis B virus (HBV) seroconversion. An accelerated dosing schedule is available but requires a total of four doses for optimal response. The combined vaccine offers the advantage of immunization against both types of hepatitis in a single vaccine.

**Immunoglobulin**

Ig is used when pre- or postexposure prophylaxis against HAV infection is needed in persons for whom vaccination is not an option. Immunoglobulin is preferred for children <12 months of age and for postexposure prophylaxis in patients aged >40 years, patients with chronic liver disease, and persons allergic to any part of the vaccine. A sterile preparation of concentrated antibodies against HAV, Ig provides protection by passive transfer of antibody. Ig is most effective if given in the incubation period of the infection. Receipt of Ig within the first 2 weeks of infection will reduce infectivity and moderate the infection in 85% of patients. Patients who receive at least 1 dose of the HAV vaccine at least 1 month earlier do not need pre- or postexposure prophylaxis with Ig.4 Ig is available both as an intravenous (IV) and IM injection but for HAV exposure, only the IM is used. If given to infants or pregnant women, the thimerosal-free formulation should be used.

International travelers are the major patient population receiving preexposure prophylaxis with Ig. HAV vaccination or prophylaxis with Ig is recommended for travelers to countries with high endemic rates of HAV. Serious adverse events are rare. Anaphylaxis has been reported in patients with Ig A deficiency. Patients who had an anaphylaxis reaction to Ig should not receive it. There is no contraindication for use in pregnancy or lactation.

Dosing of Ig is the same for adults and children. For postexposure prophylaxis and for short-term preexposure coverage of <3 months, a single dose of 0.02 mL/kg is given intramuscularly. For long-term preexposure prophylaxis of ≤5 months, a single dose of 0.06 mL/kg is used. Either the deltoid or gluteal muscle may be used. In children younger than 24 months of age, Ig can be given in the anterolateral thigh muscle.3

For people who were recently exposed to HAV and who had not been previously vaccinated, Ig is indicated in the following situations: (a) when in close personal contact with an HAV-infected person; (b) all staff and attendees of daycare centers when HAV is documented; (c) if they were involved in a common source exposure; for example, in a food-borne outbreak with an HAV-infected food handler, other food handlers at the location should receive Ig; if the case person handled food and had poor hygiene or diarrhea, patrons of the location should also receive Ig if they can be identified and located within the 2 weeks of the exposure; (d) classroom contacts of an index case patient; and (e) schools, hospitals, and work settings where close personal contact occurred with the case patient.4

Ig can be given concomitantly with the HAV vaccine. Although the antibody titer will be lower than if the vaccine were administered alone, the response is still protective. However, Ig can interfere with the response of other vaccines and should be delayed. The measles, mumps, and rubella (MMR) vaccine should be delayed for a minimum of 3 months after receipt of Ig. The varicella vaccine must be delayed for 5 months. Conversely, Ig should not be given to patients who received the MMR within 2 weeks or the varicella vaccine within 3 weeks. In situations where the benefits of Ig outweigh the benefits of the other vaccines, revaccination can be performed after Ig administration. For the MMR, revaccination should be at least 3 months later, and for the varicella vaccine, at least 5 months later.8 In general, Ig does not interfere with inactivated vaccines and may be administered safely with other vaccines traditionally given to travelers to some developing countries, such as the oral poliovirus or yellow fever vaccine.5

**PHARMACOECONOMIC CONSIDERATIONS**

Although the costs of an HAV outbreak are significant, routine vaccination of all individuals is not cost-effective. Rather, by targeting at-risk populations, the majority of cases can be prevented. Children play a pivotal role in disease persistence. The use of the HAV vaccine is cost-effective in children and offers the most benefit to the personal contacts of children, reflecting the role of children as a reservoir for the disease.16 The use of the combined HAV-HBV vaccine is effective in reducing costs associated with HAV among persons who are at increased risk for infection. Among 100,000 healthcare workers in high endemic states, the vaccine was anticipated to reduce the number of related work loss days from 34,463 to 4,667 days, an estimated savings of $6.1 million.16 Nearly $2 million in savings could be seen in costs associated with HAV treatment. In a sexually transmitted diseases clinic serving 1 million patients, the combined vaccine was expected to prevent 2,263 occult infections and cost $13,397 per quality-adjusted life-year (QALY).17 Both studies predicted between $2 million and $2.5 million in savings associated with HAV treatment, realized mostly in reduced hospitalizations. The risk of HAV from food transmission in the United States is low and can be avoided in many cases by adherence to basic hygiene practices.

**HEPATITIS B**

Although a vaccine was made available in 1981, HBV has acutely infected more than 2 billion people globally, leading to chronic infection in more than 350 million people.18 Chronic infection...
with HBV is a major public health issue as it serves as a reservoir for continued HBV transmission and poses a significant risk of death resulting from liver disease. More than 1 million people per year die as a result of liver cirrhosis and hepatocellular carcinoma (HCC).

**EPIDEMIOLOGY**

According to the CDC, only 12% of the global population lives in an area of low prevalence for hepatitis B, defined as an area where <2% of the population is HBsAg (hepatitis B surface antigen)-positive.\(^1\) Prevalence can vary regionally; however, areas commonly associated with high infectivity rates include sub-Saharan Africa, most of Asia, as well as the Amazon and southern parts of Eastern and Central Europe.\(^1\) Areas of high prevalence, approximately 45% of the global population, are of special concern because most infections are of infants and children and >90% of cases lead to a chronic carrier state. Although less than 1% of people have chronic infection in both Western Europe and North America,\(^2\) in the United States HBV is the second most common type of acute viral hepatitis and the third most reported preventable disease, second only to HAV. Rates of infection in the South are highest, however overall rates of infection in the United States continue to decline. There are approximately 1.25 million chronically infected HBV people in the United States. In 2007, an estimated 43,000 people developed new infections. Annually, 3,000 to 5,000 people die from chronic liver disease attributable to HBV.\(^1\)

HBV is transmitted sexually, parenterally, and perinatally. In areas of high HBV prevalence, perinatal transmission from mother to infant is most common, whereas in areas of intermediate prevalence, horizontal transmission from child to child is most common. Sexual contact, both homosexual and heterosexual, and injection drug use are the predominant forms of transmission in low-endemic countries such as the United States.\(^3\) Concentration of HBV is high in blood, serum, and wound exudates of infected persons. The virus is detectable in moderate quantities in semen, vaginal fluid, and saliva, and is present in low concentrations in urine, feces, sweat, tears, and breast milk.\(^4,5\) Transmission can occur through contact with infected body fluids in the absence of blood, as the virus may be stable in the environment for a number of days.\(^6,7\) In the United States in 2007, no risk factor could be identified for the majority of acute infections with HBV. Among patients with identifiable risk factors, the most common risk was sexual contact, specifically multiple sexual partners, MSM, and sexual contact with a known HBV-positive person. Sexual contact was a consistent risk among all patients but especially among those aged 45 years or younger. Other known risk factors include IDU and household contact of HBV-positive persons. A previously identified risk includes international travel, and was the largest overall risk factor in 2004 among children younger than 15 years of age.\(^8\) No cases were documented for patients receiving transfusions or on hemodialysis.\(^9,10\) Among racial and ethnic groups, HBV is highest among non-Hispanic blacks. Hispanics and non-Hispanic whites have similarly low rates, while Asians/Pacific Islanders have the lowest HBV rates.\(^1\)

The mode of transmission has clinical implications because chronic infections are associated with infection acquired in younger patients, especially those infected perinatally and in early childhood.\(^1\)

**ETIOLOGY**

The HBV is a DNA virus of the family Hepadnaviridae. It is a partially double-stranded, circular DNA with 3,200 base pairs that typically infects liver cells, although it has been found in kidney, pancreas, and mononuclear cells.\(^2,3,4\) Seven HBV genotypes exist (A to H) with distinct geographic distribution (Table 47–4). It is possible that genotype prevalence may be dependent on mode of transmission as types B and C are found in areas where vertical transmission is the primary mode of infection.\(^5\) Correlations between clinical outcomes and HBV genotypes have been suggested, with genotype C associated with more severe liver injury, including liver cirrhosis and progression to HCC.\(^2,6\) Noted limitations of studies are frequently small sample sizes and a predominance of research from Asia, primarily comparing genotypes B and C.\(^7,8\) Nonetheless, a study of a diverse patient immigrant population infected with genotypes A, B, C, D, and E, confirmed that more severe liver fibrosis was significantly higher in HBV genotypes A, C, and D-infected patients. Genotype B may be more benign because it is associated with faster seroconversion, although clinical studies suggest genotype A may have equivalent, if not higher rates of seroconversion.\(^9,20\) Resistance mutations may contribute to genotype virulence and hence impact severity of liver disease in infection.\(^21\)

**PATHOPHYSIOLOGY**

Upon infection, replication of the virus begins by attachment of the virion to the hepatocyte cell surface receptors. The particles are transported to the nucleus where the DNA is converted into closed, circular DNA that serves as a template for pregenomic RNA. Viral RNA is then transcribed and transported back to the cytoplasm where it can alternatively serve as a reservoir for future viral templates or bud into the intracellular membrane with the viral envelope proteins and infect other cells.\(^2,6\) The viral genome has four reading frames coding for various proteins and enzymes required for viral replication and spread. Several of these proteins are used diagnostically (Table 47–5). The HBsAg is the most abundant of the three surface antigens and is detectable at the onset of clinical symptoms. It is now known that some viral mutants exist that are refractory to treatment. The HBcAg is a nucleocapsid protein that, when expressed on hepatocytes, promotes immune-mediated cell death. High levels of antibodies (IgM anti-HBcAg) are detectable during acute infections. The detection of IgM anti-HBcAg is also a reliable assay for diagnosing fulminant acute hepatitis where HBsAg and

HBV DNA are often undetectable. Patients who respond to vaccine will have anti-HBsAg only.

HBV itself does not seem to be pathogenic to cells; rather, it is thought that the immune response to the virus is cytotoxic to hepatocytes. Antigen nonspecific inflammatory responses triggered by T cells may be responsible for most hepatic injury, with progression to cirrhosis and HCC. The immune response includes major histocompatibility complex (MHC) class I CD8 cytotoxic T cells and MHC class II CD4 T-helper cells. In both an acute and chronic infection, the antibody response is strong. In an acute infection, however, the cytotoxic T-cell response is critical to viral clearance. If the response is weak, chronic infection is likely. Moreover, liver injury is likely caused by secondary, nonspecific inflammation activated by the initial cytotoxic lymphocyte response and as an attempt by the immune system to clear the virus by destroying HBV antigen presenting hepatocytes. Destruction of hepatocytes results in release of circulating, and hence increased, ALT levels.

Cirrhosis

Cirrhosis results as the liver attempts to regenerate while in an environment of persistent inflammation. Like in other viral hepatitis-induced cirrholoses, continued alcohol consumption exacerbates hepatocellular damage. Most patients with compensated cirrhosis are either asymptomatic or have mild symptoms of epigastric pain and dyspepsia. During cirrhosis, the liver enters a cycle of ongoing liver damage, fibrosis, and attempts at regeneration. The classical appearance of a small and knobby liver reflects the irreversible effect of nodules of regenerating cells integrated with infiltrates of inflammatory induced fibrous tissue. Both viral and clinical factors affect the outcome of cirrhosis (Table 47–6). The development of cirrhosis is mostly insidious and patients can remain stable for years before disease progression. An estimated 20% of all chronic hepatitis B patients develop complications of hepatic insufficiency and portal hypertension as their compensated cirrhosis progresses to decompensated cirrhosis within a 5-year period. Typically, the initial clinical findings of decompensated cirrhosis are ascites, jaundice, variceal bleed, encephalopathy, or a combination of symptoms. Damage is irreversible. Treatment is supportive care and patients are candidates for liver transplantation.

Hepatocellular Carcinoma

HBV is a known risk factor for the development of HCC and in areas of high HBV endemity, a major complication of the infection. The development of HCC can be insidious, occurring in the absence of cirrhosis or in the presence of clinically silent, compensated cirrhosis. Many patients with HCC have no signs of decompensated cirrhosis. The virus itself is not likely the causative agent of the cancer. In most cases, HCC develops after years of inflammatory processes provoked by ongoing HBV infection. Compared to hepatitis C virus (HCV), however, HBV does seem to provoke a more direct carcinogenic effect as evidenced by its presence in less-severe liver disease, and among patients with advanced HCC, HBV infection is associated with a worse survival rate. Several factors influence the development of HCC, as well as predict survival (see Table 47–6). HCC is more prevalent in males; in older patients; in patients coinfected with HCV or delta hepatitis; and in patients with serologic markings of past or present HBV infection, preexisting cirrhosis, or continued alcohol ingestion. Risks for death and decompensation increase with underlying liver disease. Other host-specific or environmental factors may impact the course of liver disease. In Asian patients, HCC tumors are commonly seen in otherwise healthy patients, whereas HCC is typically seen in white patients with chronic liver disease. Persistently elevated HBV DNA levels (≥10,000 copies/mL) predict HCC development, even after adjusting for sex, age, cigarette smoking, alcohol consumption, HBsAg status, ALT level, and liver cirrhosis. HBsAg status is not a risk factor. In otherwise healthy patients without coinfection or who do not have HCC or decompensation at the time of seroclearance, HBsAg seroclearance does predict a favorable long-term outcome. Additional predictors of survival include younger age and maintenance of liver function as evidenced by laboratory findings.

HCV, hepatitis C virus; HIV, human immunodeficiency virus

Data from Fattovich, Lok and McMahon, and Wright.

CLINICAL PRESENTATION

The clinical symptoms and course of an HBV infection are indistinguishable from other types of viral hepatitis. Three phases of an HBV infection exist. During the initial or acute phase of an HBV infection in adults and older children, the HBV enters a 4- to 10-week incubation period, during which antibodies toward the HBV core are produced and the virus replicates profusely. Active viral replication results in high serum HBV DNA levels and HBeAg secretion. ALT levels may rise slightly, but most patients will remain asymptomatic. Symptoms, if they do occur, include fever,
anorexia, nausea, vomiting, jaundice, dark urine, clay-colored or pale stools, and abdominal pain. Most neonates and children are anicteric and have no clinical symptoms, whereas up to half of adult patients are icteric. HBsAg does not become detectable until after significant viremia. The initial phase is considered immunotolerant because no hepatic injury is sustained, as evidenced by generally normal ALT levels. Patients are highly infectious during this time. In perinatally acquired infections, and in young children, the phase can last for decades—until adulthood. Infected children pose a particular risk because they are often asymptomatic, undiagnosed, and highly infectious.

The immunoactive phase marks a decrease in HBV DNA levels with ongoing secretion of HBeAg. Patients are symptomatic with intermittent flares of hepatitis and marked increases in ALT levels. More frequent flares are associated with disease progression. The phase can last a few weeks in acute disease, and for years in patients with chronic disease. As the host immune system attempts to gain control of the infection by stopping active viral replication, serum HBV DNA levels drop to undetectable, ALT levels normalize, and liver necroinflammation resolves.

If the infection is self-limiting, HBV DNA quickly subsides, HBeAg disappears within weeks, and HBsAg usually resolves within 4 months. The final phase is seroconversion and is defined by the replacement of HBeAg with anti-HBeAg. Factors favoring seroconversion include female sex, older age, biochemical activity, and genotype. Flares of hepatitis with ALT levels >5 times the upper limits of normal, compared to <5 times the upper limits of normal, correspond to increased immune system activity and precede seroconversion. Some studies suggest that the A and B genotypes are associated with earlier seroconversion than genotypes C and D but the data are inconclusive and no recommendations exist for genotype testing in clinical practice.

**Chronic HBV**

Patients who continue to have detectable HBsAg and HBeAg and a high serum titer of HBV DNA for more than 6 months have chronic HBV. Table 47–7 lists the clinical features of chronic hepatitis B. The most predictive factor for developing a chronic infection is age. Perinatal infections almost always result in chronic infections because of immune tolerance to the virus. Risks of chronicity decline to a rate of 30% in infants and to less than 5% of adult acute infections.

Chronic infections can be controlled in many cases, but cure is not possible because the HBV template is integrated into the host genome. In patients with recurring cycles of viral expression and host immune response, progressive liver damage ensues. Patients can be divided into two types of chronic hepatitis B: those who are HBeAg-positive and those who are HBeAg-negative. The ability to express HBeAg by the virus differentiates the two types of chronic infection. Patients are considered to be in the “immune tolerant” phase when HBeAg is positive, high serum HBV DNA levels are detected, and ALT levels are normal. Typically these patients were infected early in life and develop elevated ALT levels later in life. Spontaneous HBeAg clearance is possible and is associated with older age, higher ALT, and infection with HBV genotype B.

Patients who are HBeAg-negative can be further subdivided into the active or inactive carrier. HBeAg-negative chronic HBV patients who are active carriers have high serum HBV DNA, elevated ALT levels, and liver necroinflammation. The clinical course tends to be worse with a very low rate of spontaneous remission. Patients may have long periods of disease remission but recurring flares of hepatitis with increased frequency and severity can progress to cirrhosis and HCC. HBeAg-negative chronic HBV patients who are inactive carriers have detectable HBsAg and anti-HBeAg, normal ALT, and either low or undetectable levels of HBV DNA. This patient population usually experiences a more benign course of disease, with the possibility of long-term remission, even seroconversion, although reactivation is possible with the progression to cirrhosis and HCC. Rarely, patients will resolve their infection. Patients with undetectable HBsAg but with anti-HBsAg and anti-HBcAg represent a small portion of patients who are not likely to experience reactivation or rechallenge because of the immunosuppressed state. Up to 20% of patients in the inactive carrier state may revert to detectable HBeAg, emphasizing the need for lifelong follow-up to confirm quiescence.

**HBV MUTATIONS**

Among the DNA viruses, HBV is notable for its significantly higher mutation rate. Long-term therapy is problematic because of the high likelihood of developing viral resistance. One of the most common mutations consists of a nucleotide substitution either preventing or causing downregulation of the production of HBeAg. The mutation results in a chronic infection that may have a poorer long-term prognosis. Typically, the mutation emerges during the infection and represents a later stage in the course of chronic HBV infection with more advanced liver disease. Variants in the precore or core promoter region are thought to be responsible for the mutation.

The selective pressures of the L-nucleoside analog antivirals, including lamivudine, cause the YMDD mutation. The mutation is associated with the active site of the DNA polymerase and causes an altered active site. The incidence of lamivudine resistance increases with each subsequent year of therapy and may be associated with a more severe disease progression. An added risk of developing resistance is the retention of the mutation within the virus even four years after lamivudine therapy. Cross-resistance of lamivudine-resistant YMDD mutants to telbivudine has been demonstrated and patients treated with lamivudine and telbivudine showed resistance mutations to both drugs. Telbivudine-specific resistance can also occur at rates lower than that seen in lamivudine. Other mutations include resistance to adefovir and entecavir. Resistance to adefovir is associated with substitutions of asparagine by threonine (rtN236T) and substitution of alanine by valine or threonine (rtA181V/T), as well as other
possible mutations to the HBV polymerase gene. The addition of lamivudine in adefovir resistance may overcome resistance, although the optimal management of either adefovir- or entecavir-resistant strains is not clear.  

PREVENTION OF HEPATITIS B

Despite the introduction of the HBV vaccine in 1981 and recommendations on vaccination in 1982, rates of HBV did not decline in the early 1980s. Initial declines in incidence were likely attributable to behavioral changes among high-risk groups as a result of the acquired immune deficiency syndrome (AIDS) epidemic. A 94% decline in rates between 1990 and 2004 was seen in children and adolescents, which began with the initiation of screening of pregnant women and subsequent immunizations of infants and recommendations set forth in the 1990s to immunize adolescents. Regulations enacted by Occupational Safety and Health Administration (OSHA) further reduced overall U.S. rates by 75%.  

Prophylaxis against HBV can be achieved by vaccination or by passive immunity in postexposure cases with hepatitis B immunoglobulin. Vaccination is the most effective strategy to prevent infection and a comprehensive vaccination strategy has been implemented in the United States (Table 47–8). Vaccines use HBsAg for the antigen via recombinant DNA technology using yeast to prompt active immunity. More than 60 million adolescents and more than 40 million infants and children have received a HBV vaccine in the United States since 1982. The vaccine is considered safe. Since 2000, vaccines licensed in the United States either contain none or trace amounts of thimerosal as a preservative. Available vaccines include two single-antigen products and three combination products. The two single-antigen products are Recombivax HB and Engerix-B. Twinrix is a combination vaccine for HAV and HBV in adults. Comvax and Pediarix are used for children and are used for HBV along with other scheduled vaccines. Passive immunity in the form of anti-HBsAg offers temporary protection against HBV and is used in conjunction with the hepatitis B vaccine for postexposure prophylaxis.

HBV infections are not curable; rather, the goals of therapy are to increase the chances for seroclearance, prevent disease progression to cirrhosis and HCC, and to minimize further injury in patients with ongoing liver damage.

GENERAL APPROACH TO TREATMENT

Response to therapy is monitored by biochemical (normalization of ALT levels), histologic examination of liver cells from biopsy (a minimum 2-point decrease in histology activity compared with baseline biopsy), and virologic response (undetectable serum HBV DNA levels and loss of HBeAg in HBeAg-positive patients). Maintenance of viral suppression is defined as durability of response. In HBeAg-positive patients, successful therapy includes loss of HBeAg status and seroconversion to anti-HBeAg. Other serologic markers are typically not evaluated in clinical trials. Recommendations for treatment consider the patient’s age, serum HBV DNA and ALT levels, as well as histologic evidence and clinical progression of disease (Figs. 47–1 and 47–2). Not all chronic HBV patients are candidates for treatment. Some patients may be best managed with periodic monitoring for disease progression because the chances for therapeutic response are unlikely and do not outweigh the risks and costs associated with treatment. Various guidelines have been published and updates made as more drugs are indicated for use in HBV.

NONPHARMACOLOGIC THERAPY

All chronic HBV patients should be counseled on preventing disease transmission. Sexual and household contacts should be vaccinated. To minimize further liver damage, all chronic HBV patients should avoid alcohol and be immunized against HBV. No level of alcohol use has been established as safe. Moreover, patients are encouraged to consult their medical provider before using any new medications, including herbas and nonprescription drugs.

Herbal medicines are an intriguing option to many patients. Four common preparations include Phyllanthus, milk thistle, glycyrrhizin (licorice root extract), and a mixture of herbs known as Liv 52. Although some of the products may have some benefits, the methodologic qualities of the trials evaluating the herbs are poor. Randomized, placebo-controlled studies and long-term followup data are lacking. Meta-analysis of existing studies demonstrated that milk thistle and Liv 52 do not affect the course of liver disease. Herbal treatment is not recommended for patients with chronic hepatitis B.

PHARMACOLOGIC THERAPY

Because hepatic damage is sustained by ongoing viral replication, drug therapy aims to suppress viral replication by either immune mediating or antiviral agents. In the United States, interferon (IFN)-α2b, lamivudine, telbivudine, adefovir, entecavir, pegylated (peg) IFN-α2a, and tenofovir are all approved as first-line therapy options for chronic HBV.

Interferon

Interferon-α2b therapy was the first approved therapy for treatment of HBV and improves long-term outcomes and survival. Acting as a host cytokine, it has antiviral, antiproliferative, and
immunomodulatory effects in chronic HBV. Several factors correlate with improved response to interferon therapy, including increased ALT and HBV DNA levels, high histologic activity score at biopsy, and being non-Asian. Asian patients tend to have more normal ALT levels in chronic infection, confounding the actual impact of ethnicity on infection.

Patients who respond to interferon therapy tend to have a more durable response than that seen with lamivudine, likely as a consequence of interferon’s stimulation of the immune response for seroconversion. Seroconversion rates range from 30% to 40% and are often permanent, although relapse is more likely in HBeAg-negative patients. The duration of therapy is finite, although the optimal duration of treatment is unclear. Treatment for a minimum of 12 months is associated with greater sustained virologic response rates than treatment for 4 to 6 months. Seroconversion can occur during or after therapy is complete. An extended treatment duration of 24 months may benefit the difficult-to-treat HBeAg-negative patient. Additional benefits of interferon-based therapies in responsive patients is a reduction in cirrhosis, HCC, and death. Conventional interferon therapy is plagued with numerous problems, including the inconvenience of thrice-weekly injections; however, standard interferon therapy has virtually been replaced by the use of pegylated interferon (peg interferon) because of the benefits in ease of administration, decreased side effect profile, and improvements in efficacy. Compared with conventional interferon, peginterferon has a longer half-life enabling once-weekly injections. For HBV treatment, the approved peg-interferon formulation is pegIFN-α2a. Studies comparing pegIFN-α2a monotherapy with peginterferon-α2a–lamivudine combination therapies suggest that combination therapy caused greater HBV DNA suppression than peginterferon-α2a monotherapy; peginterferon-α2a monotherapy better achieved HBeAg seroconversion than lamivudine monotherapy with no difference in combination therapy; and combination therapy resulted in less lamivudine resistance than lamivudine monotherapy. Interferon-based therapies are still limited by multiple adverse effects (Table 47–9). The high risk of infection precludes use of interferon in decompensated cirrhotic patients. In patients with compensated cirrhosis, interferon appears to be safe and effective, although it can provoke hepatic flares and precipitate hepatic decompensation. The optimal role of interferon-based therapies in HBV treatment is not defined.
Lamivudine

Lamivudine, a nucleoside analog, has antiviral activity against both HIV and HBV. It is dosed at 100 mg daily in adults; the optimal duration of treatment is unknown. In both HBeAg-positive and -negative patients, lamivudine demonstrates profound viral suppression. HBV DNA serum levels are undetectable in 90% of lamivudine-treated patients after 4 weeks. Normalization of ALT levels occurs gradually over 3 to 6 months in most patients. Additionally, fibrotic changes are reduced and may be reversed in some cases. Response to lamivudine is dependent on baseline ALT levels, with higher levels corresponding to greater likelihood of seroconversion. Seroconversion rates increase with duration of therapy and are at 50% by the fifth year of therapy. The advantages of lamivudine-based therapy include its safety profile and patient tolerability and the convenience of an oral tablet. Moreover, lamivudine can safely be used in immunosuppressed and cirrhotic patients. Patients who can maintain long-term viral suppression have reduced and possibly reversed cirrhotic changes. However, lamivudine therapy is not without problems. There is no clear duration of treatment and HBeAg-negative patients have a less than 20% viral suppression rate after 12 months of therapy. Serum HBV DNA levels return to baseline upon cessation of therapy. Seroconversion rates are less than 20% after 1 year of therapy and will relapse in up to 58% of patients. Relapse rates are highest among Asian patients. Resistance is inevitable and can undermine the value of treatment. The emergence of YMDD mutants increases with each subsequent year of therapy, with rates approaching 70% after 4 years of therapy, and is associated with returns of serum HBV DNA and elevated ALT levels. Relaxation is associated with reversion of histological benefits. Although seroconversion can occur even after the appearance of resistant mutants, the prognosis is poor for most patients who develop resistance. In HBeAg-negative chronic hepatitis B, where therapy is long term and the exact duration of therapy unknown, resistance is an especially daunting problem. Patients on lamivudine therapy require monitoring for breakthrough infection. If patients have confirmed lamivudine-resistant mutations, therapy should be changed to include agents with activity against lamivudine-resistant HBV.

Adefovir

Adefovir dipivoxil is an acyclic nucleotide analog of adenosine monophosphate. The drug acts by inhibiting HBV DNA polymerase. It is dosed at 10 mg daily for 1 year in adults, although the optimal duration of therapy is unknown. A 48-week course of treatment is effective in improving histologic findings, reducing serum HBV DNA and ALT levels, and increasing HBeAg seroconversion in both HBeAg-negative and -positive patients. The durability of the response is likely related to a long duration of treatment following seroconversion. Further suppression of HBV DNA and ALT levels occurred in long-term therapy over 4 to 5 years with improved histologic findings. In HBeAg-negative patients treated for 48 weeks, the benefits of therapy were lost within 4 weeks of stopping adefovir. In contrast, patients treated for 144 weeks maintained benefits throughout the treatment duration and saw continued improvement in fibrosis as the therapy continued. However, rates of seroconversion were low. Historically, increases in serum creatinine limited treatment to doses of 30 mg/day or less. In patients treated chronically at a dose of 10 mg daily, the incidence of nephrotoxicity was the same as placebo. In patients treated with 10 mg/day for a subsequent 48 weeks, the incidence of serum creatinine abnormalities did not change from the first year of therapy. Resistance to adefovir has not been seen within the first year of therapy. Resistant mutants have been identified and do respond to lamivudine therapy, although the full impact on clinical outcomes is not known. In patients with developing lamivudine resistance as demonstrated by rising HBV DNA levels, the addition of adefovir was more effective if done while ALT levels were still normal. The risk of adefovir resistance was higher among patients who were switched from lamivudine to adefovir rather than among those who had combination therapy of lamivudine and adefovir. To prevent adefovir resistance, lamivudine should be continued even in patients with lamivudine-resistant HBV, although the optimal duration for combination therapy is not known. The optimal drug therapy in adefovir resistance is not known.

Entecavir

Entecavir is a guanosine nucleoside analog that acts by inhibiting HBV polymerase. An oral agent, it is more potent than lamivudine and adefovir in suppressing serum HBV DNA levels and is effective in lamivudine-resistant HBV. Rates of HBeAg seroconversion are higher in patients with elevated baseline ALT. The drug is dosed at 0.5 mg daily for adults with treatment-naïve or non-lamivudine-resistant infections and at 1 mg daily in lamivudine-refractory patients. In a 48-week trial comparing it to lamivudine, entecavir resulted in significantly higher rates of histologic improvement, HBV DNA reduction and undetectability, and ALT normalization. No difference in HBeAg loss or seroconversion was observed in HBeAg-positive patients. In HBeAg-negative patients, entecavir showed greater histologic, virologic, and biochemical responses compared with lamivudine. Among all patients, no differences in fibrosis improvement were seen and resistance to entecavir was not detected after 2 years of therapy. However, treatment response in lamivudine-resistant patients is lower overall and entecavir-resistant mutants can develop during the course of treatment. Entecavir resistance is rare in nucleoside naïve patients; however resistance is most likely to occur in patients with preexisting lamivudine resistance and approaches 50% after 5 years of entecavir therapy in lamivudine refractory patients. Patients on lamivudine who develop resistance and are switched to entecavir should stop lamivudine therapy. Recent data suggest resistance to both lamivudine and adefovir is a risk factor for entecavir resistance. In terms of safety, entecavir is comparable to lamivudine. Patients switched from lamivudine to entecavir are at risk for hepatic flares, although severe flares are unlikely.

Telbivudine

Telbivudine is a HBV-specific nucleoside analog that acts as a competitive inhibitor of viral reverse transcriptase and DNA polymerase. The drug inhibits HBV DNA synthesis with no activity against other viruses or human polymerases. Compared with lamivudine, telbivudine is a more potent suppressor of HBV DNA with greater median HBV DNA log reductions and more patients achieving undetectable viral loads. More patients also experienced a normalization of ALT levels. Although more telbivudine-treated patients experienced seroconversion, the difference was not significant even at 2 years of therapy. Treatment failure, including an inability to suppress HBV DNA levels below

5 log, occurred statistically more often in lamivudine treated patients than in telbivudine treated ones.\textsuperscript{49} Compared with adefovir, telbivudine significantly reduced HBV DNA levels, although no difference was seen for HBeAg loss or ALT normalization.\textsuperscript{52} Resistance may limit telbivudine’s efficacy, although long-term data are needed.\textsuperscript{49} Telbivudine selects for the YMDD mutations. During a 2-year evaluation, resistance increased substantially from year 1 at 5% to 25.1% in year 2 in HBeAg-positive patients and from 2.3% to 10.8% in HBeAg-negative patients.\textsuperscript{34,55} In comparison, lamivudine resistance increased from 11% to 39.5% among HBeAg-positive patients and from 10.7% to 25.9% in HBeAg-negative patients.\textsuperscript{34,55} Varying degrees of hepatic impairment do not alter the kinetics of the drug, nor does the coadministration of lamivudine or adefovir.\textsuperscript{56,57} Combination therapy of telbivudine and lamivudine did demonstrate greater seroconversion rates but the difference was not statistically different from monotherapy.\textsuperscript{58} Telbivudine monotherapy is comparable with lamivudine in safety with few case reports of myopathy and elevations of creatinine kinase.\textsuperscript{54,55}

**Tenofovir**

Tenofovir is a nucleotide analog first approved for use in HIV and approved for HBV in 2008. It is available either as a single agent oral tablet or as a combination therapy with emtricitabine. Tenofovir is similar to adefovir but without the nephrotoxicity seen with adefovir, permitting adult dosing to be 300 mg versus 10 mg of adefovir. The higher dosing strategy likely confers several advantages to tenofovir in comparison with adefovir. Among HBeAg-positive patients, more patients treated with tenofovir had undetectable HBV DNA, ALT normalization, and loss of HBsAg than the adefovir-treated group. Rates of histologic response and seroconversion were similar. Among HBeAg-negative patients, more patients treated with tenofovir had undetectable HBV DNA, but there was no difference in ALT normalization, histologic response, and no patients lost HBsAg.\textsuperscript{59} In lamivudine-resistant chronic hepatitis B, tenofovir showed an earlier and greater suppression of HBV DNA than adefovir. There are limited data on tenofovir resistance. Tenofovir can overcome adefovir treatment failure but adefovir mutants persist, suggesting cross-resistance.\textsuperscript{60} The long-term impact of tenofovir resistance or optimal management to prevent resistance is unknown at this time. Toxicity is minimal compared with adefovir.\textsuperscript{42}

**ALTERNATIVE DRUG TREATMENTS**

Emtricitabine is a cytosine analog approved for use in HIV and with activity against HBV. It is currently not approved for HBV but has been used in combination with tenofovir. In a comparative study with placebo, emtricitabine showed a significant decrease in viral load to undetectable in 54% of patients, normalization of ALT levels in 65% of patients, and improvement in necroinflammatory score. However, seroconversion to anti-HBeAg and HBeAg loss did not differ between placebo and emtricitabine. Emtricitabine safety was comparable to placebo. At the end of the 48-week treatment, 20 emtricitabine-treated patients had YMDD or YMDD-related resistance mutations.\textsuperscript{81} Emtricitabine is similar to lamivudine and thus likely to induce similar mutations.\textsuperscript{77}

Combination therapy has been proposed to increase drug effectiveness and to counter the issues of resistance. Potential disadvantages for combination therapy include costs, toxicity, and drug interactions. Currently no data exist that combination therapy improves effectiveness. Data for preventing resistance is mixed as complete suppression of resistance has not been achieved with combination therapy. Combination therapy with interferon and lamivudine creates less resistance than lamivudine monotherapy, but the combination did not change the post-therapy viral response in comparison to interferon monotherapy.\textsuperscript{27} YMDD mutants remain susceptible to adefovir.\textsuperscript{47} Adding adefovir to patients on lamivudine when HBV DNA levels began to increase better maintained normal ALT levels and suppressed HBV DNA than waiting to add adefovir until after ALT levels increased.\textsuperscript{46} Adding adefovir to lamivudine when lamivudine resistance develops in HBeAg-negative patients was associated with improved ALT normalization and a lower likelihood for virological breakthrough or development of adefovir resistance. Both groups had similar rates of virologic response.\textsuperscript{28} In a comparison study of lamivudine monotherapy versus lamivudine-adefovir combination therapy in treatment-naive patients, similar rates of seroconversion, HBV DNA suppression, and rates of ALT normalization were observed. There was a lower rate of YMDD mutation resistance in the combination therapy group at 15% versus 43% in the lamivudine monotherapy group.\textsuperscript{28} A comparison study of telbivudine, lamivudine, or a combination of telbivudine and lamivudine did not find any benefit to combination therapy as compared with telbivudine monotherapy. Resistance was not reported.\textsuperscript{29} The American Association for the Study of Liver Disease recommends combination therapy with lamivudine or telbivudine plus adefovir, tenofovir, or entecavir for decompensated cirrhotic patients with chronic HBV regardless of HBV DNA levels or HBeAg status.\textsuperscript{30} Moreover, current guidelines suggest combination therapy with two or more agents in patients who develop antiviral resistant HBV.\textsuperscript{27}

**SPECIAL POPULATIONS**

The decision to treat cirrhotic patients depends on disease progression. Patients with decompensated cirrhosis require referral for liver transplant. Most recently updated guidelines suggest lamivudine, telbivudine, adefovir, tenofovir, and entecavir are possible agents for use in cirrhotic patients (see Fig. 47–2).\textsuperscript{27}

In patients co-infected with HCV, the clinical practice is to treat the more dominant form of the hepatitis virus. There are no current recommendations on management of HBV/HCV co-infection. Previously published recommendations suggested treating HCV according to published guidelines and to consider the addition of entecavir or adefovir if HBV DNA levels remained stable or rose.\textsuperscript{27}

Patients co-infected with hepatitis D, which requires infection with hepatitis B, may be treated with high-dose interferon alfa or peginterferon.\textsuperscript{27} There is an overall paucity of data on HBV–HDV co-infection treatment. Lamivudine has not been shown to be effective, neither has ribavirin, a drug used in combination therapy with interferon for HCV treatment.\textsuperscript{34,65}

In HIV coinfected patients, therapy should be tailored specifically to the patient. If the patient is being treated for HIV, certain regimens may be optimized to include drugs with efficacy against HBV, including tenofovir, emtricitabine, or lamivudine. If patients are on a stable regimen that does not include HBV-active drugs or are not considered for highly active anti-retroviral therapy (HAART), peginterferon-\(\alpha\) or adefovir may be used.\textsuperscript{27} Because of neutropenia associated with peginterferon-\(\alpha\), patients considered for interferon therapy should have CD4 counts >500 cells/\(\mu\)L. In patients being considered for HAART, combination therapy is recommended for HBV with either tenofovir and lamivudine or tenofovir and emtricitabine. Patients with confirmed lamivudine resistance should have tenofovir added to their regimens.\textsuperscript{27}

Although the majority of chronic HBV patients are adults, children may be treated. Lamivudine is indicated for children age 2 years and older and interferon is approved for use in children age 1 year and older. Entecavir is approved for adolescents age 16 years and older, whereas pegylated interferon and adefovir do not have indications for pediatric dosing.
PHARMACOECONOMIC CONSIDERATIONS

Cost considerations in HBV include the cost-effectiveness of the HBV vaccine and available antiviral treatments. The use of a combined HAV/HBV vaccine is cost-effective. Routine use of the HBV vaccine in HIV counseling and testing sites, including sexually transmitted disease clinics, showed it to be an effective and cost-effective measure in preventing HBV among high-risk groups. The model, which considered four different strategies in vaccination, including no vaccination, found that routine vaccination would cost $4,400 per QALY and per life-year saved. When costs of HBV treatment and transplants were included, the cost decreased to $2,200 per QALY, further supporting routine vaccination as a cost-effective measure.

The cost-effectiveness of therapy for chronic HBV patients must address the approval of new agents for treatment. For noncirrhotic chronic HBV patients with elevated ALT levels, the most cost-effective therapy consisted of initiating treatment with lamivudine and switching to adefovir with the development of lamivudine resistance. The salvage strategy cost $8,447 per QALY. Pegylated interferon was not compared. In chronic HBV patients with cirrhosis, entecavir was the most effective, yet more expensive option. Entecavir cost $25,626 per QALY as compared with adefovir’s $19,731 per QALY. Salvage therapy was not found to be cost-effective in this patient population. Pegylated interferon was not compared for initial treatment because of its relative novelty in HBV treatment; because interferon is not considered a treatment option for cirrhosis, it was not included in the analysis of cirrhotic patients.

CLINICAL CONTROVERSY

Although previously published guidelines do not support the use of IFN in cirrhosis because of the potential for an IFN-induced hepatic flare progressing to decompensation, some experts suggest peg-IFN-α2a may be an option for some patients with compensated cirrhosis. Moreover, some experts argue that lamivudine, although indicated for use in cirrhosis, may cause clinical decompensation because of the drug’s high risk for resistance and, hence, viral rebound triggering decompensation.

HEPATITIS C

HCV is approximately 5 times as common as HIV and is responsible for an estimated 10,000 chronic liver disease-associated deaths per year. More than 190,000 deaths from HCV-related disease are expected between 2010 and 2019, with projected costs exceeding $10 billion. Most acute infections are asymptomatic and the course of the infection is insidious. As a result, many patients are not diagnosed until significant disease progression.

EPIDEMIOLOGY

HCV is the most common blood-borne pathogen. In the United States, approximately 3.2 million people are chronically infected with HCV. An estimated 17,000 new HCV infections occurred in 2007; however, because of the clinically silent nature of acute infections and the 20- to 30-year disease progression to cirrhosis, it is the 200,000 patients infected per year in the late 1980s who contribute to today’s HCV burden. Considering that HCV infection is prevalent in high-risk populations such as prisoners, IDUs, and the homeless, and that this population is generally excluded from most surveys, the actual number of chronically infected people is significantly higher. Nearly 75% of infected people may not be identified. The single largest risk factor for infection is injection drug use. Some experts also consider other illicit drug use, for example intranasal cocaine, as a risk factor because of the possible contamination of drug paraphernalia not limited to syringes and needles. Historically, blood transfusion posed a major risk for infection. Patients who received blood transfusions or transplants before 1992, clotting factors before 1987, or were ever on chronic hemodialysis represent a majority of chronic HCV infections. Improved screening of blood in 1992 decreased the risk of transfusion-related HCV. Currently hemodialysis and transfusions both represent less than 1% of risk factors in known HCV exposures. Healthcare associated transmission is rare; however, a much publicized outbreak linked to an endoscopy center in Nevada in 2007 prompted an examination of HCV outbreaks associated with healthcare. Since 1998, over 58,000 patients have been screened for possible exposure to HCV in non-hospital healthcare venues, including the Nevada incident. The identified risk in Nevada was unsafe injection practices. Although sexual transmission is an often-identified risk factor, the actual risk is very low and may be confounded by other behaviors. Studies of monogamous couples in long-term relationships do not support the use of barrier methods for preventing transmission. Testing of sexual partners in a monogamous relationship is mainly recommended for ease of mind. Although sexual contact is considered an inefficient means of HCV transmission, multiple sexual partners and co-infection with sexually transmitted diseases, including HIV, increase the risk for HCV sexual transmission.

Screening

Although acute HCV infections are often not recognized and many progress to chronic infections, routine screening for infection is not recommended. Various guidelines and position papers for the screening and treatment of chronic HCV infection exist. Screening is warranted in patients who are at high risk for infection (Table 47–10). Although the risk of HCV in monogamous relationships is very low and barrier methods are not recommended, sexual partners are recommended to be tested for the sake of reassurance. The risk of infection from other needle-borne exposures, such as acupuncture, tattooing, and body piercing, is unclear and at this time not an indication for routine screening for HCV.

ETIOLOGY

HCV is a single-stranded RNA virus of the family Flaviviridae notable for lacking a proofreading polymerase and enabling frequent viral mutations. The virus replicates within hepatocytes and like hepatitis B, is not directly cytopathic. HCV replicates copiously.

ALT, alanine transaminase; HIV, human immunodeficiency virus. Data from Hoofnagle.
with an estimated serum half-life of 2 to 3 hours. The result is a proliferate, persistently mutating virus posing an immense challenge for immune-mediated control.

HCV is differentiated into six major genotypes, numbered 1 to 6, and varying in nucleotide sequence by 30% to 50%. Genotypes are further classified into subtypes (a, b, c, etc.), which differ by 10% to 30% in nucleotide sequence. The most widely distributed genotypes are 1 and 2, with genotype 1 the most common (Table 47–11). In the United States, the majority of infections are caused by genotypes 1a and 1b, followed by genotypes 2 and 3. Although infection caused by any of the genotypes can lead to cirrhosis, end-stage liver disease (ESLD), or HCC, the significance of the infecting genotype is related to therapeutic response. Genotypes 2 and 3 are at least twice as likely to respond to therapy as genotype 1. Genotypes 4, 5, and 6 are not well understood but are expected to respond with rates similar to genotype 1.

### PATHOPHYSIOLOGY

In the vast majority of cases, an acute HCV infection leads to chronic infection. The immune response in an acute HCV infection is mostly insufficient to eradicate the virus. During the early phases of infection, natural killer cells are activated as HCV RNA levels rapidly rise. A combined effort of HCV specific CD4 and CD8 T lymphocytes and interferon co-expression decrease viral replication. The eradication of HCV by cytotoxic T lymphocytes may occur either as a result of induced apoptosis by infected hepatocytes or by the release of interferon to stifle viral replication. The extent of hepatocyte apoptosis may correlate with the course of the disease. Liver damage and HCC are associated with high levels of hepatocyte apoptosis. Low levels of apoptosis are associated with viral persistence. Moreover, CD4 T-helper cells are unlikely to mediate liver injury, but rather may promote an environment conducive for other immune responses damaging to the liver. Bystander killing may also play a role in hepatic damage. Although HCV infects less than 10% of hepatocytes, up to 20% of cells are activated for apoptosis.

HCV poses a daunting challenge for immune control because of its rapid viral diversification. HCV genomic mutations are detectable within 1 year of infection. Resolved cases of HCV are defined by a vigorous T-cell response with highly active CD8 and persistent CD4 cell response. It is hypothesized that the CD8 activity mediates protective immunity but requires the aid of CD4 cells to maintain the response during viral mutations.

### CLINICAL PRESENTATION

In an acute HCV infection, most patients are asymptomatic and undiagnosed. HCV RNA is detectable within 1 to 2 weeks of exposure and levels rise quickly during the initial weeks. The HCV RNA levels plateau at 10^4 to 10^7 international units/mL and precede a peak in ALT levels and the onset of symptoms. Rising ALT levels indicate hepatic injury and cell necrosis. It is not unusual for levels to exceed values 10 times the upper limits of normal. Although HCV RNA serum levels can show interpatient variability, the levels tend to be stable for the individual patient. Typically, symptoms occur 7 weeks after the infection, with a range of 3 to 12 weeks. Approximately one third of adults will experience some mild and nonspecific symptoms, including fatigue, anorexia, weakness, jaundice, abdominal pain, or dark urine. Acute infections rarely progress to fulminant hepatitis, although the course can be severe and prolonged. If the infection is self-limiting, symptoms last several weeks as ALT and HCV RNA levels subside. Almost all patients, including immunosuppressed patients, will develop antibodies to HCV. Typically, antibodies are not detectable until either at the time of or shortly after the development of symptoms and are not used diagnostically in an acute infection because a third of infected patients may test negative at the onset of symptoms despite infection.

Up to 85% of acutely infected patients will go on to develop a chronic HCV infection, defined as persistently detectable HCV RNA for 6 months or more. HCV RNA levels and ALT levels can fluctuate and even have periods of undetectable HCV RNA and normal ALTs. Most patients will have few, if any symptoms. The most common symptom is persistent fatigue. Additional symptoms include right upper quadrant pain, nausea, or poor appetite. On physical examination, hepatomegaly is usually present. With advanced disease, stigmata of liver disease is evident, such as spider nevi, splenomegaly, palmar erythema, testicular atrophy, and caput medusae. However, almost all patients with chronic HCV will have some degree of necroinflammatory disease on liver biopsy. The extent of structural damage varies considerably. Chronic inflammation of the liver from chronic HCV infection may result in fibrosis. Fibrosis is defined by altered hepatic perfusion creating a distorted structure and affecting normal function. The speed of fibrosis progression can vary and is not necessarily predictive of cirrhosis development. An estimated 20% of chronic HCV patients will develop cirrhosis and half of those patients will progress to either decompensated cirrhosis or HCC. Historically, one third of untreated patients may expect to develop cirrhosis within 20 years, while another third of patients may delay the onset of cirrhosis for 50 years or never develop it.

It is currently not possible to definitively identify patients at risk for disease progression. Several factors may correlate with a decreased risk for chronicity. Being younger than 40 years old, female, non-black, not immunosuppressed, and with a symptomatic acute HCV infection decreases the risk of developing a chronic infection. Being older than age 20 years at infection triples the risk for chronic HCV. Blacks, especially black men, are more likely to develop chronic infection and have lower treatment responses.

Becoming symptomatic and having jaundice is associated with a lower likelihood of chronic infection, perhaps correlating to a stronger immune response to the acute infection. Finally, immunosuppressed patients, such as those with HIV, are more prone to chronic infection although they are not inherently unable to clear the infection. Recently a variation on a gene encoding for endogenous interferon has been described which is associated with a difference in response to treatment and may explain differences in response between patients of African American and European ancestry. Similarly, disease progression is associated with increased age, male sex, continued alcohol intake, obesity, and HIV coinfection. Diabetes, as well as steatosis, may also potentiate fibrosis progression. Viral load and genotypes other than genotype 3 are not factors. Genotype 3 may be associated with fibrosis progression. The development of HCV cirrhosis poses a 30% risk over 10 years for the development of ESLD, as well as a 1% to 2% risk per year of developing HCC. Progression to cirrhosis is the primary concern in patients infected with HCV for 2 decades or longer. Unfortunately, because acute infections are typically not recognized, the diagnosis of HCV is often not made until disease progression.

From Hoofnagle.
Hepatitis C Virus is a blood-borne virus that affects the liver. The most common presentation is chronic hepatitis, which can lead to cirrhosis, liver failure, and occasionally hepatocellular carcinoma. Chronic hepatitis C infection is a leading cause of liver transplantation worldwide. The virus is transmitted primarily through blood-to-blood contact, such as from intravenous drug use, needlestick injuries, and transfusion of infected blood products. In the United States, the majority of new infections are acquired through the use of injection drugs, but more than 20% of infections are transmitted through sexual contact, blood transfusions, and vertical transmission from mother to child.

**Patient Selection for Treatment**

Before initiating treatment for hepatitis C, it is important to determine the stage of liver disease. Factors considered in patient selection include age, serologic disease activity, viral load, and genotypic characteristics. Treatment is usually recommended for patients with moderate to severe hepatic grade and stage, and compensated liver disease. Patients with cirrhosis, ESLD, and HCC are considered for liver transplantation.Treatment is also indicated for patients previously untreated who have chronic HCV, developing cirrhosis, ESLD, and HCC. Moreover, HCV infection typically has advanced disease. A diagnosis of chronic HCV is confirmed with a reactive enzyme immunosassay for anti-HCV. Testing for anti-HCV is not routinely recommended because of the low prevalence of HCV in the general population and the nonspecificity of the test. Although many professional associations advocate testing for both symptomatic and asymptomatic persons with risk factors for HCV, the U.S. Preventative Task Force does not recommend routine screening of high-risk individuals.

**TREATMENT**

**Hepatitis C Virus**

**DESIRED OUTCOME**

The primary goal of therapy is to eradicate HCV infection. Resolving the infection prevents the development of chronic HCV infection sequelae including death. Even patients who are unable to achieve cure may see histological improvements with therapy.

**GENERAL APPROACH TO TREATMENT**

Treatment for HCV is necessary because nearly 85% of acutely infected patients develop chronic infections and are at risk of developing cirrhosis, ESLD, and HCC. Moreover, HCV infection is the most common indication for liver transplant. Treatment is indicated for patients previously untreated who have chronic HCV, circulating HCV RNA, increased ALT levels, evidence on biopsy of moderate to severe hepatic grade and stage, and compensated liver disease. According to the American Association for the Study of Liver Diseases, among chronic HCV patients, symptomatic cryoglobulinemia is an indication for HCV antiviral therapy irrespective of the stage of liver disease. Therapy is not without risk, and in some cases may not be recommended, such as in patients with uncompensated liver disease, a history of severe uncontrolled psychiatric disorder, and in patients with severe hematologic cytopenias. Table 47-12 lists the contraindications to therapy.

Before therapy is initiated, quantitative HCV testing, genotyping, and a liver biopsy are performed. Quantitative amplification assays for HCV RNA are performed in patients who are candidates for therapy to obtain baseline information on the viral load. A baseline HCV RNA level serves as a prognostic indicator for response and is used to monitor virologic response once therapy is initiated. Genotyping is also necessary for treatment candidates because response to therapy and duration of therapy vary depending on the infecting genotype. Liver biopsy is used to determine histologic grade and stage and to guide therapy. Because most chronic HCV patients are not diagnosed for years, a biopsy can provide clinical information on the extent of hepatic damage incurred since infection and offer baseline data to assess disease progression. In some patients, liver biopsy may support a decision to delay treatment.

Overall, the greatest predictor of treatment response is infection with nongenotype 1. Adherence to therapy is a crucial component in response, especially among genotype 1-infected patients. Patients who take at least 80% of their medications for at least 80% of the treatment time are more likely to successfully respond to therapy. Treatment response is monitored according to the following terminology:

- **Rapid virological response (RVR):** a patient with undetectable viral load at week 4 of treatment
- **Early virological response (EVR):** patient who experiences at least a 2-log reduction in viral load by the 12th week of treatment (partial EVR) or a patient with undetectable viral load by the 12th week of treatment (complete EVR)
- **End-of-treatment response (ETR):** patient with no detectable viral load at the end of treatment
- **Sustained virological response (SVR):** patient with no detectable viral load at the conclusion of therapy and 24 weeks later
- **Relapser:** patient who responds to therapy but whose viral load becomes detectable at the conclusion of therapy
- **Nonresponder:** patient with a detectable viral load after 24 weeks of therapy
- **Null responder:** patient with a viral load that never decreased by ≥2 logs after 24 weeks of therapy
- **Partial responder:** patient with at least a 2-log reduction in viral load but detectable viral levels after 24 weeks of therapy

Patients who achieve an RVR are highly likely to achieve cure; however, patients who do not achieve an RVR should not be assumed to be nonresponsive. A negative RVR does not imply inability to achieve SVR, rather it indicates patients will require a full course of therapy and potentially an extended duration of therapy. Patients who experience a complete EVR are more likely to also have an SVR. Less than 3% of patients who fail to have an EVR can be expected to achieve an SVR. Achieving a complete EVR is a better marker of SVR than achieving a partial EVR. If the goal of therapy is viral eradication and an EVR is not achieved, therapy may be discontinued at 12 weeks. In some patients, however, histologic benefits can occur without an EVR and histologic improvements alone may warrant continuation of therapy.

**NONPHARMACOLOGIC THERAPY**

All chronic HCV patients should be vaccinated against hepatitides A and B. Lifestyle changes are an important factor in reducing health consequences in hepatitis C. Continued alcohol use is a known risk factor for disease progression and severity. There is no established lower limit of alcohol consumption at which disease progression is not seen. Obesity is also a factor and patients should be encouraged to eat a balanced diet and exercise regularly to maintain a normal weight. Progression of fibrotic changes is
associated with obesity. Moreover, obesity and decreased insulin resistance contribute to decreased response to interferon. Smoking may also contribute to disease progression. Patients should be encouraged to maintain good overall health, stop smoking, and avoid alcohol and illicit drugs. The use of herbal therapy is ineffective. Patients should consult with their physician prior to initiating any herbal therapies and minimize prescriptive drug use if possible.

## PHARMACOLOGIC THERAPY

The current standard of care for chronic HCV patients is a combination therapy of a once-weekly injection of peginterferon and a daily oral dose of ribavirin. Overall response rates are greatest with combination therapy at an SVR rate of 54% to 56%. Therapy is optimized based on genotype, patient weight, and response to therapy. Table 46–13 lists current therapeutic regimens. For genotype 1, evaluation for RVR at 4 weeks is recommended as an indicator of the probability of achieving an SVR. Patients who do not achieve a RVR should be evaluated for virologic response at 12 weeks (EVR). Because therapy is not without a significant side-effect profile and because failure to achieve a complete EVR is so strongly correlated with treatment failure, some clinicians will terminate therapy early in genotype 1 patients (Fig. 47–3). Patients who achieve complete viral suppression between weeks 12 and 24 may be treated for as long as 72 weeks. Conversely, because genotypes 2 and 3 respond so well to therapy, there are data to support early treatment termination in patients who show an EVR at 4 weeks (Fig. 47–3). Current guidelines suggest patients with genotypes 2 and 3 be treated for the full 24 weeks of therapy.

### Interferon

Historically, treatment of HCV involved the use of interferon-α. Although interferon monotherapy resulted in an SVR in less than 10% of patients, the response was durable. The addition of a pegylated moiety to interferon improved the pharmacokinetic profile of the drug to reduce injection frequency from 3 times to once a week, and doubled SVR rates. Even among cirrhotic patients, peginterferon was safe and effective. Two peginterferons are available, peginterferon-α2a (Pegasys) and peginterferon-α2b (PEG-Intron). Table 47–14 lists the differences between the two drugs. It is unclear which therapy is superior. Achievement of SVR may be more likely in patients with an early and intense viral suppression. The current guidelines do not address which formulation of interferon should be preferentially used in HCV treatment.

### Ribavirin

Ribavirin, a synthetic guanosine analog, is ineffective as a monotherapy for HCV and its exact mechanism of action is unknown. When added to interferon, ribavirin significantly increases SVR rates, especially among genotypes 2 and 3. Ribavirin is dosed based on weight for optimal response in genotype 1 and 4 infections. Although monotherapy with peginterferon is an option for patients with contraindications to ribavirin, ribavirin is ineffective as monotherapy and should not be used alone. However, SVR rates are highest among patients treated with a combination of peginterferon and ribavirin at >40% for genotype 1 patients and at approximately 80% for genotypes 2 and 3.

HBV, hepatitis B virus; HCV, hepatitis C virus.
Side effects of therapy are extensive and a major obstacle to successful patient completion of therapy (see Table 47–9). Although many patients require dose reductions for laboratory abnormalities, very few result in withdrawal of therapy. In contrast, more patients prematurely stop therapy because of adverse events such as fatigue or flu-like symptoms. The most common laboratory abnormalities are neutropenia, thrombocytopenia, and anemia. Ribavirin-induced hemolytic anemia is an inevitable effect of therapy, although varying in severity among patients. Anemia results from ribavirin uptake into erythrocytes, inducing membrane damage and resulting in hemolysis. Patients may complain of fatigue as hemoglobin levels decrease even though dose reductions are not recommended until hemoglobin levels fall to 10 g/dL. The mean decrease in hemoglobin is 3 g/dL in the initial weeks of therapy; thereafter, levels stabilize until discontinuation of therapy. Hemoglobin levels normalize once ribavirin is stopped. Interferon can cause bone marrow suppression, resulting in neutropenia and thrombocytopenia. Pegylated interferons are more likely to cause neutropenia than non-peginterferon. Dose reductions are recommended for neutrophil counts <750 cells/mm; discontinuation is recommended at <500 cells/mm. However, patients are not at a greater risk for infection. Neither nadir neutrophil counts nor total neutrophil decrease from baseline are related to infection. One study examined the risk for total, viral, fungal, and bacterial infections and concluded that neither dose reductions of interferon nor the addition of granulocyte-stimulating factor in HCV-treatment-induced neutropenia is warranted.

Up to one third of patients are expected to experience some degree of depression during treatment, partly because of interferon’s interference with the serotonin pathways. Although many patients can be managed with selective serotonin reuptake inhibitors, various degrees of counseling and psychiatric consultations may be necessary. Severe depression and suicidal behaviors are rare but not undocumented. More common side effects include flu-like symptoms, which can be managed by acetaminophen or nonsteroidal inflammatory drugs.

Alternative Treatments
Currently, investigated drug treatments for chronic HCV include taribavirin, various formulations of interferon, protease inhibitors, and polymerase inhibitors. Taribavirin is a ribavirin prodrug designed to concentrate within the liver with the goal of minimizing ribavirin-induced anemia. Longer acting versions of interferon, such as albuferon, are also being investigated. Telaprevir, previously referred to as VX-950, is a reversible, selective, and specific HCV RNA protease inhibitor. It is an oral drug and current data suggest optimal dosing to be three times per day. Although telaprevir demonstrated great viral load reduction even among previous interferon nonresponders, when taken alone it demonstrated viral breakthrough within 2 weeks of initiation. Boceprevir is also a serine protease inhibitor currently being investigated in nonresponders. Early studies demonstrated profound viral suppression; however, the role of these agents will likely be as adjuncts to current therapy. Several other protease inhibitors are in various stages of development. A number of polymerase inhibitors are also in various stages of investigation. Studies in treatment-naive and treatment-refractory patients are ongoing.

Special Populations
Clinical trials are conducted with a patient population that generally does not reflect the patient spectrum encountered in clinical practice. There are no contraindications to the treatment of injection drug users, prisoners, persons with substance abuse issues, or persons with psychiatric disorders. However, barriers exist that can prevent access to care. A multidisciplinary approach to HCV treatment that includes mental health and substance abuse professionals should be considered in providing care to special populations. Published recommendations for treatment in various populations are as follows.

Patients with Normal ALTs
The decision to treat patients with normal ALTs is somewhat controversial and made on an individual patient basis. Clinicians should consider the risks and benefits of therapy, including histologic data, genotype, likelihood for response, and other factors, such as patient willingness to undergo therapy. Successful treatment significantly improves patient quality of life and reduces fatigue. Moreover, the definition of normal can vary by reporting laboratory.

Patients with Decompensated Cirrhosis
Patients with evidence of decompensation are candidates for liver transplantation. Therapy is generally not recommended unless administered by experienced clinicians. Serious adverse events including neutropenia and anemia are more likely in cirrhotics and may be managed through the use of growth factors.

Relapsed Patients
The decision to retreat should consider the previous therapeutic regimen. Patients with prior treatment with interferon monotherapy or interferon and ribavirin should be considered for retreatment with peginterferon and ribavirin. The likelihood for SVR is lower, but may be as high as 50%. Retreatment with peginterferon and ribavirin after a previously failed course of peginterferon and ribavirin is not recommended.

Nonresponders
Retreatment with peginterferon and ribavirin can increase SVR rates in patients previously treated with interferon monotherapy or interferon and ribavirin. Previous adherence, treatment tolerance, severity of underlying liver disease, as well as factors affecting treatment response, such as genotype, should be considered before deciding to retreat.

Accidental Needle-Stick Exposures
Prophylactic treatment immediately following an accidental needle-stick exposure is not recommended for multiple reasons. Risk of transmission is considered low and among those infected, a percentage will successfully seroconvert and not require treatment. Because an initial delay in therapy does not increase the risk for developing a chronic infection, most experts wait 8 to 12 weeks before initiating treatment to allow for spontaneous remission. No formal guidelines exist as the optimal duration of treatment is unknown. Treatment is suggested for 12 to 24 weeks.

Injection Drug Users
Injection drug use is a major factor in the cycle of HCV transmission. There are no recommendations against treatment for active IDUs although ongoing drug abuse can create many complications and expert opinion dictates that the decision to treat be made on a case-by-case basis. Treatment is recommended for recovering drug users, including those in drug treatment programs assuming patients are willing to comply with close monitoring and contraception requirements. Reinfec tion rates are low among injection drug users who achieve SVR. It is recommended that patients continue ongoing drug abuse and psychiatric counseling while on HCV therapy.

Alcoholism
Because continued alcohol use affects disease progression and severity and thus response to therapy, the cessation of alcohol use during therapy is recommended. Moreover, a period of abstinence before initiation of therapy is also recommended.

End-Stage Renal Disease
The role of chronic HCV treatment is not defined for patients with end-stage renal disease. Hemodialysis is a risk factor for acquiring HCV infection yet a contraindication for ribavirin use. Patients with mild renal insufficiency (GFR >60 mL/min) may be treated with combination peginterferon and ribavirin. Monotherapy with interferon is an option in patients with...
renal insufficiency or with end-stage renal disease as ribavirin is contraindicated in these patients due to risks of ribavirin accumulation and severe hemolytic anemia. Peginterferon can pose toxicity problems and requires careful monitoring.

**HIV Co-Infection** A large portion of HIV-infected patients who acquired the virus via injection drug use will be coinfected with HCV. Treatment poses additional problems because of hepatotoxicity issues associated with highly active antiretroviral treatment, hepatic complications from HIV-associated diseases, as well as flares in hepatitis as CD4 counts recover. Current guidelines recommend a 48-week course of therapy regardless of genotype. The prognosis for an SVR is worse than in patients infected with HCV only. In general, treatment is recommended and both HIV and HCV therapies can be coadministered with the exception of didanosine and zidovudine. The combination of ribavirin and didanosine can result in fatal lactic acidosis. Ribavirin causes hemolytic anemia and when combined with zidovudine can result in severe anemia.\(^*\)

**Children** Currently therapy is indicated for children age 2 years and older and consists of peginterferon-α2b dosed at 60 mcg/m\(^2\) weekly in combination with ribavirin 15 mg/kg daily for 48 weeks. Ribavirin is available in a liquid formulation. Pediatric patients tend to better tolerate therapy than adults. Pediatric patients should be evaluated as candidates for therapy similarly to the criteria for adults (Table 47–12).

**African Americans** Response rates of African Americans to HCV therapy is lower than rates observed with Caucasians and non-Hispanic whites, and genetic mutations of HCV may partially explain the discrepancies. African Americans have higher rates of chronic HCV than non-Hispanic whites and Hispanics and have greater rates of baseline neutropenia. African Americans with HCV should be evaluated for treatment and treated according to current guidelines. Baseline neutropenia (ANC <1500 mm\(^3\)) should not exclude patients from treatment.

**PREVENTION**

No vaccine is available for HCV. It is unlikely that a vaccine will be developed in the near future because of the mutagenesis of the virus. Patients infected with HCV should be counseled on not being blood, organ, or semen donors. Although the likelihood of household transmission is small, patients should minimize risks by avoiding possible blood or mucus exposure, such as not sharing razors or toothbrushes and covering open wounds. Patients who continue to use illegal drugs should avoid sharing all drug paraphernalia, as risk of transmission is not limited to needles and syringes.

**PHARMACOECONOMIC CONSIDERATIONS**

The progression of HCV-induced liver disease is highly variable and identifying which patients will progress remains a clinical challenge. Because not all patients will develop clinical sequelae, therapy may not be necessary in all patients. Given the relative unreliability of treatment to achieve an SVR, the costs associated with therapy, and the side-effect profile of the drugs, the cost-effectiveness of therapy may be questioned. Several studies have assessed the economic values of treating chronically infected HCV patients.

Issues of cost-effectiveness must weigh the public health impact of HCV against the costs of therapy. Despite the decreased incidence of acute HCV infections, epidemiologic data suggest the greatest disease burden will occur in 2015, reflecting the slow progression of disease in patients infected in the late 1970s and early 1980s. At the same time, HCV-related mortality is expected to triple.\(^*\) A projected 720,000 patient-years will be lost as a result of decompensated cirrhosis and HCC. Predicted costs exceed $21 billion from the development of clinical sequelae. In patients who are younger than age 65 years, the costs associated with premature death are even higher—an expected $54 billion.\(^*\) Although not all patients will develop HCV-related liver disease, it is not currently possible to identify which patients will have disease progression. Moreover, HCV-infected patients are prone to high levels of fatigue and neuropsychiatric and cognitive impairment, further contributing to decreased patient quality of life.\(^*\)

Treatment with peginterferon therapy compared with traditional interferon is a cost-effective approach among noncirrhotic patients who are infected with any of the genotypes, especially in patients who are infected with nongenotype 1.\(^*\) A review of studies published on the cost-effectiveness of therapies for HCV found that HCV therapy is cost-effective most of the time. Reduced cost-effectiveness was seen in patients treated with normal transaminases and healthy biopsies. However, most clinicians would opt not to treat such patients. Moreover, evaluating virologic response by week 12 and terminating therapy if no response is evident substantially lowers treatment costs by more than $15,000. Overall, various studies found that HCV treatment falls within the accepted cost-effectiveness margin, defined as less than $50,000 per QALY. The studies concluded that antiviral therapy costs offset costs associated with disease sequelae.\(^*\)

**CLINICAL CONTROVERSIES**

In patients with advanced disease, a biopsy may be risky and offer no additional clinical information of whether to treat or not. Some clinicians believe that if therapy is to be initiated regardless, the liver biopsy offers no additional information. In patients with genotype 2 or 3, because response to therapy is so high and most clinicians treat despite biopsy results, there may not be a reason for biopsy.

Histologic improvement is not limited to patients who experience an SVR. Some clinicians believe interferon-based antiviral therapies, regardless of response, can decrease the incidence of HCC development.

Although ribavirin dosing is different for the treatment of genotype 1 depending on the formulation of pegylated interferon, most clinicians will dose ribavirin according to patient weight, irrespective of the formulation.

New data from clinical practice studies in Europe suggest peginterferon-α2a may achieve greater rates of SVR in genotype 1 patients. Data are in abstract form and contradict a recently published trial.

Drug Therapy Individualization in Patients with Hepatic Disease and Genetic Alterations in Drug Metabolizing Activity

Y. W. FRANCIS LAM

KEY CONCEPTS

1. Hepatic elimination of drugs is primarily dependent on three variables: activity of metabolizing enzymes, plasma protein binding, and liver blood flow, each of which could be altered significantly in patients with liver diseases.

2. Hepatic extraction ratio represents a conceptual measure of the efficiency of extraction of drug from the blood by the liver, and is not a measure of the metabolic capacity of the liver per se.

3. Increased systemic bioavailability is primarily a concern for orally administered drugs that have a high hepatic extraction ratio.

4. Both phase I and II enzymes have been associated with altered drug exposure.

5. Evaluation of patient’s liver function for assessment of need of dosage adjustment is difficult, with most clinicians opting for use of the Child-Pugh classification.

6. Genetic polymorphisms affecting the drug metabolizing enzymes represent an additional patient-specific factor to consider in optimization of drug therapy.

7. There are few examples of how metabolic genotypes or phenotypes can determine dosage of individual drugs.

8. There have been increased attempts to incorporate pharmacogenetics in clinical studies during drug development and in regulatory review.

Although there are different patient-related variables that can change the pharmacokinetics of drugs and potentially require dosage regimen modification, the most common dosing changes likely occur with alterations in elimination capacity of the two primary eliminating organs, the liver and the kidneys. This chapter will focus on the changes in drug pharmacokinetics and pharmacodynamics resulting from altered hepatic drug metabolism in patients with hepatic dysfunction, and the implications for dosing. In addition, genetic changes in metabolic capacity of the patient also affect drug elimination from the liver, and examples of how pharmacogenetics have impacted dose modification and labeling is discussed in this chapter.

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.

DRUG ELIMINATION BY THE LIVER

1. Drugs are primarily eliminated from the body by metabolism and excretion. The liver plays a pivotal role in the metabolism of drugs and formation of metabolites prior to their excretion by the kidneys. The overall capacity of the liver to carry out its metabolic role is primarily dependent on three factors: activity of the metabolizing enzymes within the smooth endoplasmic reticulum and the cytosol of the hepatocyte; the degree of drug protein binding in the blood, which affects the amount of unbound drugs available for uptake into the hepatocyte; and liver blood flow, which delivers drugs to the hepatocyte via the portal vein for orally administered drugs and via the systemic circulation for drugs administered by other routes. Thus, patient-specific factors that affect enzymatic activity, protein binding, or liver blood flow would potentially result in significant alterations in drug disposition and therapeutic response. An understanding of the pharmacokinetic basis of hepatic drug elimination/metabolism is a foundational premise from which one can conceptualize and quantify altered drug disposition in patients with liver dysfunction.

PHARMACOKINETIC BASIS OF HEPATIC DRUG CLEARANCE

Only unbound drugs can be transported from the vasculature to the hepatocyte, where biotransformation, which is dependent on the activity of the relevant metabolic enzymes occurs. Therefore, blood flow to the liver, the degree of plasma protein binding, and the intrinsic metabolic activity, all affect the efficiency of the liver to metabolize a specific drug. The intrinsic metabolic activity, defined as the ability of the hepatocyte to eliminate a given drug in the absence of drug supply limitations such as plasma protein binding and blood flow, reflects the inherent activity of the relevant drug metabolizing enzymes and is quantified as intrinsic clearance ($\text{Cl}_{\text{int}}$). The hepatic clearance ($\text{Cl}_{\text{H}}$) is related to the three physiological determinants by the following mathematical relationship:

$$\text{Cl}_{\text{H}} = \frac{Q_H \times f_u \times \text{Cl}_{\text{int}}}{Q_H + f_u \times \text{Cl}_{\text{int}}}$$

where $Q_H$ is hepatic blood flow and $f_u$ is unbound drug fraction in the blood.

Based on this mathematical relationship, when enzyme activity ($\text{Cl}_{\text{int}}$) and $f_u$ are very low relative to hepatic blood flow, they will become the primary determinants and rate limiting process for hepatic clearance, as $\text{Cl}_{\text{H}} \sim f_u \times \text{Cl}_{\text{int}}$. On the other hand, when enzyme activity and $f_u$ are very high in relation to blood flow, $\text{Cl}_{\text{H}}$ would approximate hepatic blood flow and be the rate limiting process for hepatic clearance. A more detailed discussion of the complex mathematical relationship between hepatic clearance and the three

physiological determinants, as well as the different pharmacokinetic models used to explain the physiological approaches to hepatic drug clearance, are provided in the review by Wilkinson.1

2 The hepatic clearance for any drug can also be conceptualized as the product of blood flow across the liver and the hepatic extraction ratio (ERH) for that drug. The ERH is a semi-quantitative measure of the efficiency of extraction of drug from the blood by the liver that has a numerical value that ranges from zero to 1. High-extraction ratio drugs which have an ERH ≥0.7 are readily cleared from the blood and more sensitive to changes in, and rate-limited by, hepatic blood flow. Examples of high-extraction ratio drugs with this flow-dependent elimination characteristic are metoprolol, nitroglycerin, and verapamil. Low-extraction ratio drugs—those with an ERH ≤0.3 are more sensitive to changes in the degree of plasma protein binding and/or intrinsic metabolic activity, and rate-limited by these two factors rather than by hepatic blood flow. They are thus also considered to demonstrate flow-independent elimination. Warfarin, diazepam, and valproic acid are representative examples of low-extraction ratio drugs (Table 48–1).

Although it seems confusing that extensively metabolized drugs such as warfarin, phenytoin, and theophylline are classified as “low-extraction” drugs, it is important to remember that the ERH does not measure metabolic capacity per se, rather it is a conceptual semi-quantitative measure to help define the ease of extraction of a drug by the liver as the drug is delivered to the hepatocyte. Based on the degree of plasma protein binding, drugs with low-extraction ratio are sometimes further subgrouped as binding sensitive (e.g., phenytoin) and binding insensitive (e.g., theophylline). As such, the mathematical relationship discussed in the preceding paragraph would dictate that hepatic clearance of a highly protein-bound, low-extraction ratio drug would depend on both intrinsic clearance and the degree of plasma protein binding; in contrast, the intrinsic clearance of a drug that is minimally bound to plasma proteins is the primary factor affecting its hepatic clearance.

### ALITED HEPATIC DRUG CLEARANCE IN LIVER DISEASES

Based on the overview of the pharmacokinetic basis of hepatic drug clearance, changes in drug metabolism can result from alterations in hepatic blood flow, plasma protein binding, or intrinsic metabolic activity. While many different pathophysiological liver diseases can result in reduced functional capacity, most acute entities such as hepatitis, liver cancer, and hepatosplenic schistosomiasis are usually not associated with significant or prolonged alterations in drug metabolism. Jorga et al.2 showed that in patients with moderate chronic hepatitis, there was no difference in the unbound clearance of tolcapone compared with that in healthy volunteers. In contrast, patients with nonalcoholic cirrhosis showed a significant decrease in unbound clearance of tolcapone. In fact, most clinical studies that have investigated the effect of liver diseases on drug disposition have primarily been conducted in patients with cirrhosis.3

### CHANGES IN HEPATIC BLOOD FLOW

3 The liver is primarily perfused by blood from the hepatic artery, which carries oxygenated blood from the aorta, and the portal vein, which carries nutrient-rich blood from the gastrointestinal tract. The terminal branches of the hepatic artery and the portal vein merge into the hepatic sinuses and serve as the vascular capillaries of the hepatocyte. The hepatic vein is the conduit by which blood from the liver enters into the inferior vena cava and then the systemic circulation. The portal vein provides about 75% of the liver’s total blood supply of about 1.5 L/min in healthy adults. Therefore, the liver is the first site of metabolism for orally administered drugs even before they reach the systemic circulation (Fig. 48–1). This “first pass effect” primarily affects high extraction ratio drugs and the extent of drug elimination can be significant, resulting in low systemic bioavailability (Table 48–1). Simply put, under the assumptions of complete drug dissolution, absence of drug degradation in the gastrointestinal tract, and absence of gut wall metabolism, a drug with ERH of 70%, will have a bioavailability of 30%. Although the extent of drug metabolism can be circumvented by oral administration of a higher dose compared with that for intravenous administration, the oral bioavailability of some drugs could be very low and variable, necessitating administration by alternative routes such as the sublingual route for nitroglycerin.

In patients with cirrhosis, due to any of the multiplicity of causes (see Chapter 43), blood flow across the liver is usually decreased.4,5 In addition, cirrhosis also causes alteration of vasculature within the liver, resulting in intra- and extra-hepatic portosystemic shunting. Shunt formation has been shown to allow up to 80% of blood supply to bypass the hepatocytes,4 and thus does not come in contact with the metabolizing enzymes located therein. Furthermore, the permanent loss of hepatocyte function in patients with cirrhosis also results in reduced metabolic capacity. These two pathological processes together decrease hepatic clearance significantly for orally administered high extraction ratio drugs, and the reduced first pass effect results in a dramatic increase in systemic bioavailability (Table 48–1).3 Pentikainen et al.4 reported that in patients without cirrhosis, the oral bioavailability of midazolam is 38%. In patients with cirrhosis, the bioavailability is 76%, representing a two-fold increase. This can have
a significant impact on the likelihood of the patient experiencing an adverse drug reaction and warrant dosage adjustment for patients with liver diseases which will be discussed later in this chapter. In contrast, low-extraction ratio drugs tend to have minimal first pass effects and therefore exhibit high bioavailability after oral administration. As long as additional biological processes, such as gastrointestinal absorption, are not altered then bioavailability will be minimally affected.

CHANGES IN METABOLIC CAPACITY

In addition to altering the liver vasculature, cirrhosis also has been associated with irreversible hepatic damage and cell death. Although extensive hepatic damage is associated with reduced drug metabolism as evidenced by a decrease in Cl\textsubscript{int}, the extent of impairment is variable not only among patients, but also among different metabolic enzymes.

In general, phase I oxidative metabolism meditated by the cytochrome P450 (CYP) enzyme system is more sensitive to the effect of cirrhosis than phase II conjugation reactions, especially glucuronidation. For example, among the benzodiazepines, the clearance of diazepam and midazolam, but not of oxazepam and temazepam, are reduced in patients with cirrhosis. This differential effect between phase I oxidation and phase II conjugation reactions may be related to greater sensitivity of the CYP enzyme system to hypoxia as the result of impaired uptake of oxygen caused by sinusoidal capillarization. Indeed hypoxia has been shown to have an important role in suppressing CYP-mediated drug metabolism in both animal and human studies. Frommes et al. have shown that oxygen administration via a face mask in cirrhotic patients resulted in normalization of clearance of the phase I substrate theophylline but not of acetaminophen, a phase II substrate. Other factors that may contribute to the variable sparing effect include activation of latent UDP-glucuronosyltransferase (UGT), increased extrahepatic glucuronidation, differences between specific glucuronidation pathways, and similar to the CYP enzyme system, a differential effect on individual UGT isoforms. Despite the general belief of “sparing” of phase II conjugation reactions in patients with cirrhosis, it is important to note that more recent studies have shown conjugation reactions can be reduced in patients with liver dysfunction, especially those with severe liver cirrhosis (Table 48–2).

The conflicting result between the study of Sonne et al. and Shull et al. could be related to the difference in severity of liver diseases in the two study populations.

Given the presence of multiple isoforms of human cytochrome P450 enzymes, different studies have investigated whether there are selective differences in expression and activity of individual isoenzymes. George et al. found that the total CYP amount in the livers obtained from 50 patients with different degrees of end-stage liver disease, Child-Pugh class A to C, was reduced when compared with healthy individuals. Based on the Child-Pugh classification, four of the 50 patients had class A, 17 had class B, and 29 had class C cirrhosis. In addition, 18 patients also had cholestasis.

Selective and variable alterations in amount, catalytic activities, and mRNA level among CYP1A2, CYP2C8/10, CYP2E1, and CYP3A were reported in these 50 patients, and the presence or absence of cholestasis also had an effect on the observed changes. CYP1A2 amount and catalytic activity were significantly reduced with a corresponding decrease in mRNA level in patients with both cholestatic and noncholestatic cirrhosis. CYP3A4 amount, catalytic activity, and mRNA were significantly reduced only in patients without cholestasis. The amount and catalytic activity of CYP2E1 were decreased only in cirrhotic patients with cholestasis, whereas the CYP2E1 mRNA level was lower in both types of cirrhosis. In contrast, CYP2C8/10 amount and catalytic activity were not reduced in either type of cirrhosis. Although the corresponding levels of mRNA were shown to be decreased in both cirrhosis types, the use of a nonspecific polyclonal antibody to identify CYP2C8/10 might have recognized other 2C isoenzymes and produced erroneous results. In summary, while it is clear that based on in vitro studies at the protein level, the extent of hepatic dysfunction-induced impairment in drug metabolism is dependent on both severity and type of disease, as well as the specific isoenzyme affected, the exact mechanism for this differential effect remains to be elucidated. In addition, the ability to extrapolate these results to the patient care setting and possible dosage recommendation would likely require incorporation of the effect of additional patient-specific variables such as concurrent medications and disease states.

CHANGES IN EXTENT OF PLASMA PROTEIN BINDING

An additional complicating factor occurs for low-extraction, protein-binding sensitive drugs. In patients with cirrhosis, production of drug-binding proteins such as albumin and alpha-1-acid glycoprotein are decreased, resulting in an increase in the unbound concentration of acidic and basic drugs, respectively. The magnitude and duration of the elevated unbound concentration is difficult to predict.

BILIARY EXCRETION AND HEPATIC TRANSPORT OF DRUGS

The biliary tract is important not only for bile secretion, but also for excretion of drugs and metabolites mediated by the APT-binding cassette superfamily of hepatic transporters. Drugs and metabolites that are excreted into the bile reach the small intestine via the biliary tract. Within the small intestine, these metabolites, especially the glucuronides, can be converted back to the parent compound, resulting in reabsorption of both parent and metabolites and thus complete the enterohepatic circulation. Therefore, interruption of this enterohepatic circulation could reduce systemic drug exposure. There is little information on the contribution of biliary excretion to the overall drug elimination and the effect of liver diseases on biliary excretion of drugs is poorly quantitated.

The role of hepatic transport proteins in mediating drug uptake into the hepatocytes and biliary excretion of drugs has been recognized in recent years. Among these hepatic transporters, the organic
anion transporting polypeptide (OATP) and the P-glycoprotein multidrug transporter, or MDR1, have been the most studied. OATP is an uptake transporter which is responsible for the hepatic uptake of organic anions primarily, whereas P-glycoprotein is an efflux transporter that is responsible for the biliary excretion of cationic drugs. Although different human diseases are known to be associated with loss of transporter function, currently there is little specific information regarding how liver disease affects the function of these proteins and therefore hepatic transport in humans. Nevertheless, reduced expression of transporters including OATP2 and MRP2 have been observed in patients with cholestatic liver diseases, which could impair excretory liver function. On the other hand, intermittent hypoxia could up-regulate hepatocellular P-glycoprotein expression.

**ADDITIONAL EFFECTS OF LIVER DISEASES ON DRUG DISPOSITION AND EFFECTS**

**EFFECT ON DRUG ABSORPTION**

Delayed gastric emptying possibly related to altered action of gastrointestinal hormones, has been shown to occur in patients with cirrhosis. While this will delay the rate of absorption, the extent of drug absorption is generally not reduced. Although the liver has no functional role in affecting the absorption of drug from the gastrointestinal tract per se, its unique anatomical positioning within the circulating system makes it a primary site of loss for orally administered drug prior to its entry into the systemic circulation. As previously discussed, drugs with a high extraction ratio tend to undergo significant “pre-systemic metabolism” or “first pass effect,” resulting in low systemic bioavailability. In patients who have cirrhosis with associated portasystemic shunting and/or reduction in metabolic capacity, oral administration of these drugs could result in a significant increase in their systemic bioavailability and hence pharmacodynamic effect. In contrast, drugs with low extraction ratios have been noted to be negligibly affected.

**EFFECT ON DRUG EXCRETION**

Reduced glomerular filtration rate and renal plasma flow have been observed in patients with liver cirrhosis and patients with liver transplant, potentially accounting for reported decreased renal elimination of commonly used drugs. In addition, in individual patients, advanced liver disease can be complicated by the presence of hepatorenal syndrome. In these patients, dosage reduction would need to be considered even for drugs that are primarily excreted unchanged by the kidney. For example, the elimination of the anti-epileptic agent levetiracetam is primarily dependent on the kidney, yet a 50% dosage reduction was recommended for patients with severe cirrhosis. It is difficult to assess renal function in patients with liver cirrhosis. Most serum creatinine-based equations tend to overestimate the true glomerular filtration rate. This has led some investigators to suggest the use of inulin or iothalamate to measure GFR in patients with advanced liver diseases.

**EFFECT ON DRUG PHARMACODYNAMICS**

Changes in therapeutic response to a drug can occur in patients with liver disease even in the absence of any changes in pharmacokinetics. Increased drug sensitivity can occur as a result of altered affinity of the drug to its target, altered binding to the target, alteration in the target itself, altered permeability of the blood brain barrier, or increases in GABA-ergic activity or GABA receptors. Altered pharmacodynamic responses have been reported in the literature with analgesics, benzodiazepines, loop diuretics, and beta-blockers.

Bakti et al. reported that with similar unbound triazolam concentration at 2.25 hours after drug administration, cirrhotic patients have an average of 30% greater impairment in psychometric performance tests, including digit symbol substitution test, flicker sensitivity, and pursuit rotor, when compared with healthy control subjects. Test performance was similar in both groups prior to administration of triazolam. The study results suggest that the increased sensitivity is not due to altered pharmacokinetics and might explain why clinically some cirrhotic patients develop encephalopathy and other CNS effects even when administered standard doses of benzodiazepines, cimetidine, and quinolones.

On the other hand, resistance to the pharmacodynamic effects of loop diuretics in patients with cirrhosis has been reported for bumetanide, furosemide, torasemide, and triamterene. For these drugs, the sigmoidal curve that describes the relationship between drug concentration and pharmacological response is shifted to the right, indicating a reduced response compared with healthy individuals. Down-regulation of β2-adrenoreceptors in patients with cirrhosis has been suggested as a possible mechanism of lower therapeutic response observed with metipranolol in patients with cirrhosis.

**LIVER FUNCTION ASSESSMENT**

In contrast to renal impairment, accurate quantification of liver function in patients with hepatic impairment is difficult to perform, especially for the purpose of drug dosage adjustment. The severity of liver function impairment is usually assessed clinically with the Pugh modification of the Child-Turcotte classification. Based on the clinical evidence of ascites and encephalopathy and laboratory parameters that measure the liver’s synthetic and excretory functions, patients are assigned different scores in accordance to the level of impairment in these parameters (Table 48-3). This classification is easy to use and useful for following the clinical course of an individual patient or comparing groups of patients among studies. It is noteworthy that the Child-Pugh classification does not include assessment of renal function, an important prognostic factor in liver disease. The Model for End-stage Liver Disease (MELD) is a more recently developed, and potentially more objective scoring system for liver disease severity and includes variables such as serum bilirubin, creatinine, and the international normalized ratio (INR) of prothrombin time. However, alterations in the synthesis of albumin

A value of 5 suggests absence of liver impairment, whereas 15 would indicate severe liver failure. Child-Pugh class A = 5 to 6 points, class B = 7 to 9 points, and class C = 10 to 15 points. The original Child-Turcotte classification consisted of grades A, B, and C, with grade C being the most severe liver disease. Similar to the Pugh modification, the Child-Turcotte classification includes albumin, bilirubin, and ascites, plus assessment of nutrition and neurological disorder.
or clotting factors and the corresponding changes in their respective laboratory parameters as well as the presence of patient-specific variables such as nutritional status and vitamin K intake complicate the utility of these parameters in the MELD functional assessment tool. In addition, in contrast to renal impairment, none of the clinically used liver function tests, including those used in the Child-Pugh classification and MELD, correlate well with drug pharmacokinetic parameters. This not only is a result of their inability to quantify the primary physiological determinants of hepatic clearance, including intrinsic clearance and hepatic blood flow, but also a reflection of the complex and multiple physiological processes not being accurately accounted for by any individual laboratory test.

The inability of endogenous markers to provide a quantitative measurement of the liver capacity to metabolize drugs has led to the administration of exogenous model substrates and calculation of their clearances or the extent or rate of formation of their respective metabolite as quantitative liver function measurements. Based on the physiological determinants of hepatic clearance discussed previously, these exogenously administered model substrates can be generally categorized into flow dependent, e.g., indocyanine green, lidocaine, and sorbitol; and flow independent, e.g., aminopyrine, antipyrine, caffeine, and erythromycin. However, none of these markers have been shown to be better than the Child-Pugh classification for assessing liver function in patients. The time required for performing these tests, as well as the invasiveness of some of the procedures associated with specific tests, also limit their clinical utility. Indeed, to date, they have not gained widespread acceptance for predicting drug kinetics and aiding dosage adjustment in patients with liver dysfunction.

Furthermore, studies showed that administration of a flow-dependent and flow-independent model substrate in the same subject did not result in an independent measure of the physiological determinants of hepatic clearance. Rather, a correlation between the two test measures was unexpectedly obtained. Since cirrhosis causes both irreversible hepatic cell damage and altered vasculature via portasystemic shunting, the pharmacokinetic profile of a drug can be affected by changes in hepatic blood flow and drug metabolizing enzyme activity. However, it is not known to what extent reduced hepatocyte function would impact elimination of flow-dependent drugs. Nevertheless, the “intact hepatocyte hypothesis,” which suggests the presence of intra-hepatic shunts in chronic liver disease, has been proposed as a possible explanation for the reduced extraction of flow-dependent drugs. This may account for the observed positive correlation between the clearances of both flow-dependent and flow-independent drugs. In addition, given the complexity of the CYP enzyme system, simultaneous administration of several model substrates which have specificity for different metabolic enzymes has been advocated and can be accomplished by the administration of various combinations of drugs. This so-called “cocktail approach” has been primarily used in the research environment to characterize changes in metabolic capacities in patients with liver dysfunction.

**DRUG DOsing IN PATIENTS WITH LIVER IMPAIRMENT**

Similar to dosing considerations in patients with kidney dysfunction, drug dosage regimen adjustment in patients with liver diseases can in general be accomplished by either dose reduction, extending the dosing interval, or a combination of both strategies. However, the lack of a clinical laboratory test that correlates well with the metabolic capacity of the liver has hampered the development of dosing guidelines or algorithms. The U.S. Food and Drug Administration (FDA), through official guidance, has suggested the need of dosage adjustment for drugs that exhibit a greater than two-fold increase in AUC in patients with hepatic impairment, although no specific recommendation (e.g., percentage dose reduction or extent of liver impairment) has been provided.

Nevertheless, based on an understanding of the pharmacokinetic basis of hepatic drug metabolism, knowledge of the likely etiology of liver dysfunction (reduced liver blood flow, porta-systemic shunting, or hepatic failure), and characteristics of the drug in question (flow dependent or flow independent, extent of plasma protein binding), a conceptual framework for rational dosing can be made. For orally administered drugs with a high ERH, the initial and maintenance doses in patients with cirrhosis need to be reduced because of the likely significant decrease in first pass effect caused by porta-systemic shunting and decreased hepatic blood flow. The challenge in adopting this conceptual framework to clinical practice is our inability to predict the magnitude of dose reduction needed. Given the data of Pentikainen and the ranges of reported percentage increase in bioavailability for some commonly used drugs (Table 48–1), one prudent approach is to assume 100% bioavailability unless there is specific bioavailability data or dosage adjustment recommendations. If this is the case one can estimate the reduced maintenance dose proportionally by using the following mathematical expression: Dm/Dn = F/100, where F is the known bioavailability of the drug in patients without liver disease available from the literature or the manufacturer, and Dm and Dn are the doses used in patients with liver dysfunction and normal liver function, respectively. If drugs with a high ERH were administered intravenously, then only the maintenance dose would need to be reduced as a result of reduced hepatic blood flow. For drugs with a low ERH changes in bioavailability is minimal after oral administration and the initial dose for both oral and intravenous routes could be the same as patients with normal liver function. On the other hand, the maintenance dose for both administration routes would need to be reduced in patients with cirrhosis based on the estimated reduction in metabolic capacity.

For example, the oral dose of theophylline can be reduced by up to 50%, because the clearance is 0.042 L/kg/h in patients with cirrhosis as compared with 0.062 L/kg/h in patients with normal liver function. Similarly, the dosage of tolcapone also is recommended to be reduced by 50% because of the difference in unbound clearance in patients with Child-Pugh class B cirrhosis relative to normal volunteers. Obviously, this dose modification strategy serves only as a starting point. The therapeutic index of the drug in question and good clinical judgment with an awareness of other factors that can further change the metabolic capacity (for example, in the case of theophylline, viral illness, smoking, drug—drug interaction, congestive heart failure) would greatly enhance the ability of a clinician to optimize drug therapy in patients with liver dysfunction.

Since there is no equivalent of serum creatinine or creatinine clearance for assisting dosage adjustment in patients with liver dysfunction, the Child-Pugh classification, despite its limitation, is still used primarily by clinicians to assess the extent of liver dysfunction and dose adjustment if needed. Since a total Child-Pugh score of 5 and 15 represent, respectively, normal liver function and severe hepatic impairment, it is reasonable to reduce the maintenance dose by 25% for a drug that is primarily dependent on the liver for elimination (≥65% to 70%) in a patient with a score of 8 to 9. A dose reduction of at least 50% would be prudent for a patient with a score of ≥10. Likewise, Child-Pugh B and C classifications could result in similar 50% and 75% reductions, respectively, of the daily maintenance dose. For both classification systems, depending on the severity of the liver dysfunction and clinical judgment, extension of the dosing interval should also be considered. Again, based on the assumption of 100% bioavailability, the extended dosing interval can be estimated proportionally by the following mathematical expression: Tm/Tn = F/100, where F is the known bioavailability of the drug in patients without liver disease available from the literature or the manufacturer, and Tm and Tn are the dosing intervals...
used in patients with hepatic dysfunction and normal liver function, respectively.

Since the FDA official guidance recommends the use of the Child-Pugh classification to categorize the extent of hepatic impairment in patients, this classification has been employed during drug development as the foundation for the development of dosage recommendations for patients with liver diseases. For example, two- to four-fold increases, respectively, in the AUC of atomoxetine in patients with Child-Pugh B and C classifications, have led to the labeling recommendations of 50% and 75% reduction of the normal dose used in patients with normal liver function. A summary of dosage recommendations for 23 recently approved drugs has been published; however, the utility of these data to guide drug therapy decisions in clinical practice is unknown.

PHARMACOGENETIC ALTERATION IN DRUG METABOLIZING ENZYME ACTIVITIES

While many factors, including age, gender, smoking, and diet, can influence drug disposition and therapeutic response in individual patients, recent research emphasis has focused on the effect of pharmacogenetics on drug pharmacokinetics and pharmacodynamics. For a more in-depth discussion of the concept of pharmacogenetics and how drug disposition and response are related to specific genotypes and/or phenotypes, please refer to Chapter 9. In that chapter, there is also a tabulation of the most commonly utilized diagnostic substrates for those drug-metabolizing enzymes which exhibit genetic variability. The focus of the subsequent sections of this chapter is to provide information on how pharmacogenetic testing has been reported in the literature and its impact on drug therapy individualization or labeling changes for those drugs that are metabolized by polymorphic enzymes.

Pharmacogenetic testing to identify the presence of altered metabolic activity can be achieved by phenotyping and/or genotyping. In general, a genotype is a trait marker of an individual’s metabolic activity for a specific polymorphic enzyme and is independent of time and external factors such as concurrent medications, smoking status, or diet. Phenotyping, on the other hand, represents the metabolic activity at a specific time, which could be susceptible to changes associated with concurrent drug therapy. For most patients receiving concurrent therapy, the phenotype might be the more useful and relevant assessment of metabolic capacity and, hence, the foundational information to guide dosing considerations. For example, in the presence of a potent CYP2D6 inhibitor, the CYP2D6 metabolic capacity of a genotypic extensive metabolizer (EM) could be significantly decreased to a level similar to that of a poor metabolizer (PM). In such a scenario, the metabolic capacity would be more accurately reflected by the phenotype, and the dose of the given CYP2D6 substrate drug in a genotypic EM might need to be reduced.

DOSING IN PATIENTS WITH GENETICALLY ALTERED METABOLIC CAPACITIES

ALTERATION IN PHASE ONE ENZYMES

**CYP2C9**

Metabolism of the pharmacologically active S-warfarin is almost exclusively mediated by the polymorphic CYP2C9, with the *3 allele having a greater influence on its disposition than the *2 allele. A meta-analysis of 39 studies involving 7,907 genotyped patients reported that racemic warfarin doses in patients carrying either of these two allelic variants were 20% to 78% lower compared to those with the wild-type *1 allele. Athal et al. and Margaglione et al. reported higher incidence of bleeding complications in patients with the *2 or the *3 allele compared with patients with the *1 allele. While these studies demonstrate a role for the CYP2C9 polymorphism in determining warfarin dose requirement and minimizing toxicity, polymorphisms in other target genes could also be relevant. Examples of additional polymorphisms include those affecting the activities of vitamin K 2,3-epoxide reductase complex, subunit 1 (VKORC1), γ-glutamyl carboxylase, epoxide hydrodase, calumenin, and protein C, as well as the uptake of vitamin K. Incorporation of the relevant covariates of warfarin dosing in dosing algorithm could further optimize warfarin dosing in clinical practice. Of these, the VKORC1 polymorphism is mostly defined, with the G/G genotype as the homozygous wild-type requiring higher warfarin doses than G/A and A/A genotypes. Current data suggest that both VKORC1 and CYP2C9 are major determinants of warfarin dose, whereas the other genes contribute up to 10% of variation.

In August 2007, the FDA revised the warfarin product label to include pharmacogenetic information, and subsequently approved different genetic tests for warfarin dosing. A recent study using a pharmacogenetic algorithm that incorporated clinical and genetic data to estimate initial dose of warfarin showed better correlation between predicted dose and actual dose requirement, in particular for patients requiring low (≤21 mg/wk) and high (≥49 mg/wk) doses, than a clinical algorithm or a fixed-dose approach. Two recent studies utilized modeling techniques to simulate the potential clinical and economic outcomes of pharmacogenomic-guided dosing in hypothetical patient cohorts treated with warfarin for the first time, and concluded that the relatively high cost ($326 to $570 for CYP2C9 and VKORC1 bundled testing) of genotype-guided dosing is associated with modest improvements with respect to quality-adjusted life-years, survival rates, and total adverse event rates. Nevertheless, the investigators also suggested that cost-effectiveness of pharmacogenomic-guided warfarin dosing could be improved in several ways. This includes decreasing genotyping cost by 50%, achieving greater effectiveness in INR-control in clinical outcomes (quality-adjusted life-years, survival rates, and total adverse event rates) with genotype-guided dosing, and applying the genotype-guided dosing algorithm in patients with out-of-range INRs and/or at high risk for hemorrhage.

**CYP2C19**

Despite the fact that CYP2C19 mediates the metabolism of several drugs, including proton pump inhibitors (PPIs), diazepam, and voriconazole, its clinical utility has not been examined as extensively as that of the CYP2D6 polymorphism. The polymorphic CYP2C19 is the primary isoenzyme responsible for the metabolism of PPIs. Although there are up to 10-fold differences in systemic exposure between carriers of the CYP2C19*1 allele versus *2 and *3 alleles, patients possessing one or two of these variant alleles did not experience higher incidence of concentration-related toxicity. This is likely a reflection of the wide margin of safety for these drugs. Rather, the clinical relevance of the CYP2C19 polymorphism is related to the efficacy of PPIs in erradicating *H pylori*. Compared with CYP2C19 PMs, higher PPI doses are required in CYP2C19 EMs to achieve similar drug exposure, intragastric pH, and efficacy. Similar to CYP2D6*2, a recently identified CYP2C19*17 allele is
associated with a very rapid metabolism phenotype and carriers of this allelic variant would likely require higher doses of PPIs for acid suppression.\textsuperscript{59,60} Although one study showed no association between CYP2C19*17 genotype and eradication of H pylori for pantoprazole,\textsuperscript{41} another study predicted that omeprazole AUC would be lower by about 40\% in homozygous carriers of CYP2C19*17.\textsuperscript{55} Given the higher affinity of omeprazole to CYP2C19 compared with pantoprazole,\textsuperscript{63} further studies using omeprazole are required to clarify the clinical relevance of CYP2C19*17 genotype in determining the success rate of treatment of acid-related disorders.

Furata et al.\textsuperscript{64} reported the results of pharmcogenomic-based tailored lansoprazole regimens designed to achieve sufficient acid inhibition for eradication of H pylori. Based on 24-hour intragastric pH monitoring in healthy volunteers, lansoprazole dosage regimens that achieved intragastric pH ≥5.0 were documented to be 30 mg 3 times daily for homozygous carriers of the *1 allele, 15 mg 3 times daily for heterozygous carriers of the *1 allele, and 15 mg twice daily for homozygous carriers of the *2 or *3 alleles. For achieving intragastric pH ≥5.8, the corresponding dosage regimens in the three CYP2C19 genotypes were 30 mg 4 times daily, 15 mg 4 times daily, and 15 mg twice daily, respectively. Three hundred H pylori-positive patients were then randomly assigned to receive either the standard regimen consisting of lansoprazole 30 mg, clarithromycin 400 mg, and amoxicillin 750 mg, all given twice daily; or the pharmaco-genomics-based regimen consisting of lansoprazole dosed according to patient’s CYP2C19 genotype and antibiotic regimen according to genetic testing of bacterial susceptibility to clarithromycin. The eradication rate for the pharmacogenomics-based regimen was 96\% (144 of 150 patients), significantly higher than the 70\% (105 of 150 patients) achieved with the standard regimen (P < 0.001). Including the cost of the genotyping test, the per-patient cost for successful eradication of H pylori for the genotype-based regimen ($669) was similar to that of the standard regimen ($657), lending support not only to the clinical usefulness, but also the cost-effectiveness of pharmacogenomic-based therapeutic approach as well.

CYP2C19 polymorphism has also been associated with dosing of the antiplatelet drug clopidogrel, which requires biotransformation to its active metabolite. In 162 healthy subjects, those with at least one reduced-function CYP2C19 allele had 32.4\% lower AUC of the active metabolite, reduced inhibition of platelet aggregation, and decreased pharmacological response (P < 0.001). In addition, in 1,477 patients with acute coronary syndromes, higher incidences of cardiovascular events following myocardial infarction were noted in patients with reduced CYP2C19 function when compared with noncarriers of the reduced-function alleles.\textsuperscript{65} This and six other studies were cited in the revised clopidogrel FDA-approved product label (updated May 5, 2009) which noted a 30\% to 50\% reduction in AUC of the active metabolite in CYP2C19 intermediate and poor metabolizers after a loading dose of 300 or 600 mg and a maintenance dose of 75 mg daily.\textsuperscript{65}

\section*{CYP2D6}

The report of a female patient found to be resistant to normal doses of nortriptyline\textsuperscript{66} represented one of the earliest indications of how altered metabolic capacity can impact drug dosing and response. The clinical observation and subsequent metabolic phenotyping and genotyping identified three extra copies of the CYP2D6 gene in the patient,\textsuperscript{67} thereby accounting for her extremely high dose requirement of 500 mg/day. This patient and others with similar high CYP2D6 activity were subsequently categorized as ultrarapid metabolizers (UM).

This clinical observation led to a dramatic increase in the identification, cloning, and investigation of the functional significance of numerous additional CYP2D6 alleles. To date, it is probably safe to label CYP2D6 as the most studied but yet most variable gene. The presence of multiple alleles with significant interindividual (20\%–96\%) and intra-individual (12\%–140\%) variabilities in enzyme activity\textsuperscript{68,69} may be partially responsible for the time gap between the nortriptyline case report and subsequent attempts to utilize metabolic genotype or phenotype to generate antidepressant dose recommendations.\textsuperscript{70} The investigators compared the pharmacokinetic profiles of 32 CYP2D6- and CYP2C19-dependent antidepressants in subjects with an array of CYP2D6 and CYP2C19 genotypes. The analysis took into consideration the contribution of the polymorphic isoenzymes to the overall elimination of each antidepressant, and provided dose recommendation for 14 of the 32 antidepressants in EMs, intermediate metabolizers (IMs), and PMs of CYP2D6 (Table 48–4) or CYP2C19. In general, PMs need about 50\% of normal dose of tricyclic antidepressants, whereas the dose reduction was smaller for the selective serotonin reuptake inhibitors (SSRIs).

Using the approach proposed by Kirchheiner et al.,\textsuperscript{71} nortriptyline maintenance dose requirements for attainment of comparable systemic exposure were estimated to be 50\% in PMs and up to 230\% of the average dose in UM. Though there are multiple literature reports of increased incidence of antidepressant adverse effects in PMs of CYP2D6, there were no other documented reports of therapeutic failure for CYP-dependent antidepressants in EMs. Kirchheiner et al.\textsuperscript{71} acknowledged the lack of data preclude any dose recommendation in UM for most antidepressants, with the exception of nortriptyline, desipramine, and mianserin. They further noted that only five of 54 reviewed studies included evaluation of efficacy in relation to genotypes, and only the study of Mihara et al.\textsuperscript{72} showed a significant relationship (P = 0.023). More recently, Brockmoller et al.\textsuperscript{73} reported that the clearance of S-mirtazapine in UM was 12.6-fold higher than in PMs, and suggested that poor response might occur in UM as a result. Although this data suggests the need for a higher dosage for UM, no specific recommendations were made.

The formation of the active metabolite O-desmethyltramadol from tramadol is dependent on CYP2D6, and similar to codeine, analgesic relief from tramadol has been reported to be lower in PMs.\textsuperscript{71} Although tramadol also possess other opioid and non-opioid-dependent mechanisms for its analgesic effect, Stamer et al.\textsuperscript{74} have shown in a prospective study of 300 patients recovering from abdominal surgery, a significant difference in the percentage of nonresponders (based on need for rescue pain medication and patient’s satisfaction upon interview) between CYP2D6 PMs (46.7\%) and EMs (21.6\%)
(P = 0.005). They also reported a difference in the postoperative analgesic dose requirement of tramadol between the two groups: 144.7 ± 22.6 mg in PMs and 108.2 ± 56.9 mg in EMs (P < 0.001). In the recovery room 43.3% of genotypic PMs compared with 21.6% of genotypic EMs required rescue medication. The authors concluded that PMs required higher analgesic consumption to achieve pain relief. Even though there are likely other significant pharmacogenetic variables affecting opioid analgesic response, the difference in dosing requirement shown in this study suggests that 30% dose increases might be necessary in patients who are CYP2D6-poor metabolizers. Similar to the PMs, the presence of CYP2D6*10 allele in intermediate metabolizers has also been associated with reduced tramadol efficacy.79

The anticancer drug tamoxifen is metabolized by CYP2D6 to its active metabolite endoxifen. Recently, a robust correlation between the CYP2D6 genotype and endoxifen concentration was noted; PMs had a reduced relapse-free time and disease-free survival rate.76,77 Although many studies had tested for an association between the CYP2D6 genotype and clinical response to tamoxifen, most of the trials involved a relatively small number of patients. Currently, the FDA has not revised the product label of tamoxifen.

**CLINICAL CONTROVERSY**

Currently there is no consensus about the use of CYP2D6 genotyping testing in patients prescribed tamoxifen. Some clinicians advocated its use, especially in postmenopausal women who are CYP2D6 PM, where aromatase inhibitors would be a valid alternative therapeutic choice. Opponents of the practice argue that routine use of the genotype test should await more reliable evidence from well-designed studies. On the other hand, the clinical implication of CYP2D6 metabolic status is more relevant for prescribing concurrent therapy that might interact with tamoxifen via CYP2D6 inhibition. When prescribing antidepressants in breast cancer patients for management of depression and/or vasomotor symptoms, choice of antidepressants should take into consideration their inhibitory effect on CYP2D6.46,78

**CYP3A**

Despite the existence of significant interindividual variability in activity, evaluations of the role of CYP3A genes (CYP3A4, CYP3A5, and CYP3A7) in mediating disposition and response have not been conclusive. The most convincing evidence showing a genetic influence on tacrolimus pharmacokinetics has been demonstrated in patients with the *3 allele of CYP3A5*3. Homozygous carriers of the *3 allele had a higher plasma tacrolimus concentration compared to patients with the CYP3A5*1 allele, although considerable overlap was noted.79,80 MacPhee et al.81 showed that homozygous and heterozygous carriers of the CYP3A5*1 allele required a longer time to achieve therapeutic concentrations and suggested these individuals be prescribed an initial tacrolimus dose that is twice normal. Given that it is common clinical practice to measure tacrolimus concentrations, this genotype-based dose modification recommendation could be readily tested. Based on current pharmacogenetic information, dosing information cannot be predicted nor are dosage modifications recommended for cyclosporine or sirolimus.82

**ALTERATION IN PHASE 2 ENZYMES**

**Thiopurine Methyltransferase**

6-Mercaptopurine and azathioprine are used in the management of childhood acute lymphoblastic leukemia and autoimmune and inflammatory diseases such as rheumatoid arthritis. S-methylation of these drugs is mediated by the polymorphic thiopurine S-methyltransferase (TPMT). PMs and IMs with two and one deficient TPMT allele, respectively, are prone to significant hematopoietic adverse effects when given standard doses. Currently, it is well established that PMs and IMs would need a minimum of 10% to 15% and 50%, respectively, of the normal dose of thiopurines.88 The identification of a patient’s TPMT genotype prior to therapy initiation has been adopted as a standard procedure in some hospitals in the United States.84 In a recent study, Fargher et al.89 reported that 67% of National Health Service clinicians in England routinely utilize TPMT phenotyping compared with approximately 5% who use genotyping to guide prescribing and monitoring of azathioprine. Investigators reported that screening for TPMT gene mutations for all patients prior to starting azathioprine is cost-neutral if only homozygous carriers of the mutation suffer from myelosuppression. Screening would become cost beneficial if heterozygous carriers of the mutations also experienced myelosuppression.90 Additional documentation of cost-effectiveness of the strategy,90,91 expanded education of clinicians, and further availability of commercial tests for determination of TPMT genotype and phenotype may make it easier to justify and implement genotype-based thiopurine dosing into clinical practice.

**Uridine Diphosphate Glucuronosyltransferase**

The uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1) is involved in the glucuronidation of several anticancer drugs including irinotecan. Irinotecan is a prodrug and the pharmacologically active moiety, SN-38, is inactivated by UGT1A1. Thus, PMs of UGT1A1 have a higher incidence of dose-limiting toxicities.92 A prospective clinical pharmacogenetic study has shown a correlation between the development of grade 4 neutropenia and patients who are homozygous carriers of the UGT1A1*28 allele.93 In fact, the product label for irinotecan has been updated to reflect the need of reducing initial dose by at least one level (e.g., from 230 mg/m² to 125 mg/m²) in homozygous carriers of the UGT1A1*28 allele (Table 48–4).

**N-Acetyltransferase**

The bimodal distribution of isoniazid’s acetylation capacity, which was demonstrated several decades ago, explained the higher incidence of peripheral neuropathy and hepatotoxicity seen in slow acetylators (SAs) compared with rapid acetylators (RAs).94 Years later, genotyping studies confirmed an inverse relationship between the numbers of active NAT2 allele and the risk of hepatotoxicity: 28-fold and 4-fold increases in relative risk were noted for patients with no active and one active NAT2 allele, respectively, when compared to patients with two active NAT2 alleles.95,96 Currently two large phase III studies of isoniazid in European and Asian countries are enrolling patients to determine the utility of NAT genotype-based dosing (2.5 mg/kg twice weekly for SAs and 7.5 mg/kg twice weekly for RAs) in reducing toxicity in SAs and early treatment failure in RAs. The trials are expected to be completed in late 2011 to early 2012. (See Isoniazid Dose Adjustment According to NAT2 Genotype, http://www.clinicaltrials.gov.)

**POTENTIALS, CHALLENGES, AND LIMITATIONS OF PHARMACOGENETIC SCREENING AS A PHARMACOTHERAPY DOSSING TOOL**

The above cited examples suggest that there is great potential value associated with the use of pharmacogenetic screening of patients to optimize therapy. The value of early detection of patients with deficient metabolic genotype and/or phenotype is clearly demonstrated with the thiopurines and irinotecan, whereas clinical experience with nortriptyline96,97 and ondansetron98 showed that optimal therapeutic response can be achieved earlier in UM. Given the data on poorer
Examples of Label Changes Incorporating Pharmacokinetic Data or Therapeutic Response in Patients with Liver Diseases

- Despite the expanding body of beneficial evidence, the pace of incorporation of pharmacogenetic-guided individualized therapy into clinical practice has been slow. Currently, pharmacogenetic screening for deficiency in TPMT is one of the few examples of how pharmacogenetics can enhance the individualization of thiopurine drug therapy. The updated product labels of irinotecan and clopidogrel lack specific and quantitative information regarding dose reduction for homozygous or heterozygous carriers of the respective reduced-function alleles and to date genotype-based dosing information is not available for most other drugs. Given the extensive literature on genotype-related differences in drug pharmacokinetics, the incorporation of dosing information into clinical practice has been slow. For example, clearance of tolbutamide in homozygous CYP2C9*1/*1 allele carriers have about 50% lower clearance. Based on these results, dose reductions of about 90% and 50% would seem to be an appropriate recommendation for patients with intermediate TPMT activity, whereas heterozygous carriers of the *2 allele have about 50% lower clearance. Based on these results, dose reductions of about 90% and 50% would seem to be an appropriate recommendation in these patients for controlled clinical trials to evaluate whether the goal of genotype-based therapy could be achieved in clinical practice. However, to date, such a prospective trial has not been carried out. Since efficacy of the oral sulphonylureas can be evaluated easily in clinical practice, implementation of these dose recommendations in clinics or physician’s office in lieu of expensive and time consuming clinical trials might be the first step to take in achieving pharmacogenetic-based dosing and therapy individualization.

Yet it is clear that not all drugs are candidates for genotype-guided dose recommendation. The drug in question not only has to be primarily metabolized by a polymorphic enzyme, it also needs to have a narrow therapeutic index. Based on the knowledge of their pharmacology, the SSRIs would not be good candidates, and it is not surprising that the Evaluation of Genomic Applications in Practice and Prevention Working Group does not recommend the application of pharmacogenetics for these agents. However, in the study of Brockmoller et al., although there was a trend towards lower haloperidol efficacy in UMs and higher efficacy in the PMs, there was significant overlap in the haloperidol daily doses among the four metabolic groups, with 14 ± 10 mg in UMs versus 13 ± 9 mg in the PMs. This could be due to the complex metabolic disposition of haloperidol that includes CYP2D6- and CYP3A4-mediated oxidation, glucuronidation, and interconversion with reduced haloperidol. The clinical utility of CYP2D6 genotyping is further minimized by significant interethnic variabilities in metabolic disposition, and possibly the difficulty of relating rating scale-based changes in psychotic symptoms to specific metabolic genotypes. In addition, as demonstrated with risperidone, the presence of an active metabolite would also make it difficult to demonstrate the clinical relevance of genotype-based dose recommendation for the parent compound.

Nevertheless, it is encouraging to find that pharmaceutical companies have chosen to include pharmacogenetic screening to identify special populations for evaluation of pharmacokinetics, pharmacodynamics, and clinical outcomes during the drug development process. As an example, CYP2D6 genotype was one of the patient-related variables included in the evaluation of differences in systemic exposure of atomoxetine and an 8- to 10-fold increase in AUC and higher incidence of adverse effects was noted in the PM population. Although no specific dose recommendation arose from the results, the information was incorporated into the drug labeling. As additional data regarding the clinical relevance of pharmacogenetic screening for dosing and therapy individualization become available, the information can be incorporated not only for drugs in development but also for drugs that have been approved. It is noteworthy that over the years, the FDA has updated the product labels of more than 200 drugs to include pharmacogenetic information. This information is in general divided into three categories: pharmacogenetic test either (1) required or (2) recommended for therapeutic decision making, and (3) the availability of pharmacogenetic test is for information purposes only. Specifically, the labeling of 5-mercaptopurine, azathioprine, irinotecan, and clopidogrel were revised to reflect the risk of toxicity and/or the lack of efficacy, as well as the need of dosage adjustment in PMs and IMs. The FDA has also approved the AmpliChip CYP genotyping test (Roche Diagnostics) for screening of common CYP2C19 and CYP2D6 alleles, and the UGT1A1 Molecular Assay (Third Wave Technologies) for genotyping UGT1A1 alleles. However, due to lack of study data using patients’ individualized genotypes, the revised label information does not specifically address the precise dose reduction for patients receiving any of these drugs (Table 48–5).

CONCLUSION

Pharmacogenetics has the potential to improve drug therapy in patients. However, variations in multiple genes that affect both the pharmacokinetics and pharmacodynamics of the candidate drugs present significant challenges in identifying specific gene-variant combinations that can help clinicians achieve optimal therapeutic outcomes for their patients. In addition, few studies address the cost-effectiveness of genomic-guided dosing. Additional clinical trials, similar to the study of Furuta et al.64 and the ongoing NAT2 genotype-guided treatment evaluation need to be done before pharmacogenetics-guided dosing can be routinely recommended in clinical practice.

Celiac Disease

ROBERT A. MANGIONE AND PRITI N. PATEL

KEY CONCEPTS

1. Celiac disease is a chronic, inflammatory autoimmune disorder caused by intolerance to ingested gluten, a storage protein found in wheat, barley, and rye, and other foods when a genetically predisposed person is exposed to the environmental trigger, gluten.

2. Celiac disease is common in Europe and North America, affecting between 1 in 100 to 1 in 120 adults, and 1 in 80 to 1 in 300 children.

3. The integrity of the tissue junctions of the intestinal epithelium is compromised in patients with celiac disease; this enables gluten to reach the lamina propria. The presence of gluten in the lamina propria and an inherited combination of genes contribute to the heightened immune sensitivity to gluten that is found in patients with celiac disease.

4. The classic presenting symptom in adults is diarrhea, which may be accompanied by abdominal pain or discomfort; however, it is noteworthy that during the last decade it has been reported that diarrhea has been the main presenting symptom of celiac disease in less than 50% of cases.

5. Dermatitis herpetiformis is a skin manifestation of celiac disease. All patients with celiac disease will not develop dermatitis herpetiformis; however, all patients with dermatitis herpetiformis are considered to have celiac disease.

6. The frequency of diagnosis of patients with celiac disease has increased; however, the majority of patients with this condition remain undiagnosed.

7. A confirmed diagnosis of celiac disease requires both positive findings on duodenal biopsy and a positive response to a gluten-free diet. The most common serologic markers that are used for screening patients are serum immunoglobulin (IgA) endomysial antibodies and IgA serum anti-tissue transglutaminase antibodies.

8. Clinicians must evaluate the patient with celiac disease for nutritional deficiencies (including folic acid, vitamin B12, fat-soluble vitamins, iron, and calcium) due to malabsorption. Iron-deficiency anemia may be the only presenting sign of disease in patients without diarrhea.

9. Celiac disease is a chronic, inflammatory autoimmune disorder caused by an intolerance to ingested gluten, a storage protein found in wheat, barley, and rye. Genetic, environmental, and immune factors all play a role in the development of celiac disease. The mainstay of treatment of the disease is strict adherence to a gluten-free diet.

A disease resembling celiac disease was first described by a Greek physician in the second century AD.¹ In the mid-1900s, the connection between the ingestion of cereals and celiac disease was made. For many years, celiac disease was considered a disease of childhood with primarily gastrointestinal symptoms. It is now recognized as a disease of all ages with varied presentation.

Also known as celiac sprue, nontropical sprue, and gluten-sensitive enteropathy, the disease is characterized by both gastrointestinal and extraintestinal symptoms. Chronic inflammation caused by exposure to gluten leads to gastrointestinal discomfort, nutrient malabsorption, and systemic complications. Gastrointestinal symptoms, including diarrhea, cramping, bloating, and flatulence, are the “classic” symptoms; however, a patient with celiac disease may initially present with a variety of extraintestinal symptoms. Patients with silent celiac disease have no or minimal symptoms but manifest mucosal damage on biopsy and have positive serologic testing. Patients with celiac disease classified as latent are asymptomatic patients who may show positive serology, have the human leukocyte antigen (HLA)-DQ2 and/or DQ8 haplotype, but have normal mucosa on biopsy.²

Adherence to a gluten-free diet is essential because it improves symptoms and prevents long-term complications of celiac disease, which include T-cell lymphomas, small bowel adenocarcinoma, and esophageal and oropharyngeal carcinomas.³

CHAPTER 50
Clinical Assessment of Kidney Function

THOMAS C. DOWLING

KEY CONCEPTS

1. The stage of chronic kidney disease (CKD) should be determined for all individuals based on the level of kidney function, independent of etiology, according to the National Kidney Foundation (NKF) Kidney Disease/Dialysis Outcome Quality Initiative CKD classification system.

2. Persistent proteinuria indicates the presence of CKD.

3. Quantitation of urine protein excretion, such as the measurement of a spot urine albumin-to-creatinine ratio, is recommended for determining the severity of CKD and monitoring the rate of disease progression.

4. The glomerular filtration rate (GFR) is the single best indicator of kidney function.

5. Measurement of the GFR is most accurate when performed following the exogenous administration of inulin, iothalamate, or radioisotopes such as technetium 99m diethylenetriamine pentaacetic acid (99mTc-DTPA).

6. Equations to estimate creatinine clearance or GFR are commonly used in ambulatory and inpatient settings and incorporate patient laboratory and demographic variables, such as serum creatinine, cystatin C, age, gender, weight, and ethnicity.

7. Longitudinal assessment of GFR and proteinuria is important for monitoring the efficacy of therapeutic interventions, such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, which are used to slow or halt the progression of kidney disease.

8. The measurement of \( S_C \) alone, evaluation of a plot of the reciprocal of \( S_C \) versus time, and serum cystatin C concentration should be used with caution to estimate the rate of decline in renal function in patients with CKD, as these indices do not consider patient age, lean body mass, gender, diet, concomitant diseases and drug therapy, circadian rhythm, stability of kidney function, or tubular secretion of creatinine.

9. Other assessments of the kidney, such as radiography, computed tomography, magnetic resonance imaging, sonography, and biopsy, are mainly used for determining the diagnosis of a given condition, as they provide evidence of the functional and structural changes associated with kidney disease.

Chronic kidney disease (CKD) is an increasingly alarming worldwide health concern, with nearly 2 million people in the United States alone estimated to require hemodialysis or kidney transplantation by 2030. In response to this widespread problem, the National Kidney Foundation (NKF) has developed a standardized approach for the identification and classification of individuals with CKD and their subsequent stratification into risk categories for end-stage renal disease (ESRD) (see Chapter 52). These efforts have heightened the awareness of the need for early identification of patients with CKD and the importance of monitoring kidney function in the clinical setting.

Assessment of renal function using both qualitative and quantitative methods is an important part of the evaluation of patients and an essential characterization of individuals who participate in clinical research investigations. Estimation of creatinine clearance (CL\(_C\)) has been considered the clinical standard for assessment of renal function for more than 40 years; however, new methods to estimate the glomerular filtration rate (GFR) are now used in many clinical settings to identify patients with CKD. Other tests, such as urinalysis, radiographic procedures, and biopsy, are also useful for determining the pathology and etiology of kidney disease. Urinalysis, for example, may give clues to the primary location (e.g., glomerular or tubular) of the renal disease. Follow-up studies, such as imaging procedures and kidney biopsy, may then further differentiate the specific cause, thereby guiding the selection of the optimal therapeutic intervention.

10. Quantitative indices of GFR or CL\(_C\) are considered the most useful diagnostic tools for the identification of the presence of CKD. These measures can also be used to quantify changes in function that may occur as a result of disease progression, therapeutic

Learning objectives, review questions, and other resources can be found at www.pharmacotherapyonline.com.
intervention, or a toxic insult. The measurement or estimation of creatinine clearance, however, remains the most commonly used index for individualizing medication dosage regimens in patients with acute and chronic kidney disease. Furthermore, CL C has been the chief index used to stratify patients in pharmacokinetic studies that serve as the basis for the design of renal dosing algorithms in Food and Drug Administration (FDA) approved package inserts and tertiary drug information sources. The composite term renal function includes the processes of filtration, secretion, and reabsorption, as well as endocrine and metabolic functions. Alterations of all five renal functions, whether declining or improving, are associated primarily with GFR. This chapter critically evaluates the various methods that can be used for the quantitative assessment of kidney function in individuals with normal renal function, as well as in those with CKD and acute renal failure (Table 50–1). Where appropriate, discussion regarding the qualitative assessment of renal function is also presented, including specialized tests such as kidney biopsy.

### EXCRETORY FUNCTION

The most important contribution of the kidney to overall maintenance of body homeostasis is the urinary excretion of water, electrolytes, endogenous substances such as urea, and environmental toxins. Through the combined processes of glomerular filtration, tubular secretion, and reabsorption, the nephron, as the functional unit of the kidney, regulates the output of water, electrolytes, and solutes from the body and is the key organ responsible for maintenance of homeostasis despite fluctuations in dietary ingestion.

### FILTRATION

Glomerular filtration is a passive process by which water and small molecular weight ions (<5–10 kDa) and molecules diffuse across the glomerular capillary membrane into the Bowman capsule and then enter the proximal tubule (Fig. 50–1). Because most proteins are too large (>60 kDa) to be substantially filtered, or their filtration is impeded by the electronegative charge on the epithelial surface of the glomerulus, compounds presented to the glomerulus in the protein-bound state are not filtered and thus remain in the peritubular circulation.

---

**FIGURE 50-1.** Structures of the (A) urinary system, (B) kidney, and (C) nephron, the functional unit of the kidney.
SECRETION

Secretion is an active process that mainly takes place in the proximal tubule and facilitates the elimination of compounds from the renal circulation into the tubular lumen. Several highly efficient anionic and cationic transport systems for a wide range of endogenous and exogenous substances have been identified, and the renal clearance of these actively secreted entities can greatly exceed GFR; for example, their clearance may be in the range of 600 to 1,000 mL/min (10–16.7 mL/s). Probenecid, p-aminohippurate (PAH), and penicillin are examples of anionic substances; creatinine, cimetidine, and procainamide are well-characterized cations. Other transport pathways, such as P-glycoprotein and multidrug resistance protein, are also present in several tissues, including the kidney, liver, jejunum, colon, and brain. These efflux proteins are now recognized as important contributors to the renal elimination of many drugs. For example, P-glycoprotein, which is located on the apical membrane of the proximal tubule, plays an important role in the renal elimination of a wide range of drugs, such as cimetidine, digoxin, and procainamide. Blockade of P-glycoprotein could result in decreased renal elimination of such compounds, leading to an increased drug exposure. Verapamil and cyclosporine are the two most widely studied agents that reduce the activity of this tubular transport mechanism. The net process of tubular secretion for drugs is therefore likely a result of multiple secretory pathways acting simultaneously.

REABSORPTION

Reabsorption of water and solutes occurs throughout the nephron, whereas the reabsorption of most medications occurs predominantly along the distal tubule and collecting duct. Urine flow rate and physiochemical characteristics of the molecule influence these processes: highly ionized compounds are not reabsorbed unless pH changes within the urine increase the fraction unionized, so that reabsorption may be facilitated.

INTACT NEPHRON HYPOTHESIS

The intact nephron hypothesis described by Bricker, which was published more than 40 years ago, proposes that kidney function of patients with renal disease is the net result of a reduced number of appropriately functioning nephrons. As the number of nephrons is reduced from the initial complement of 2 million, those that are unaffected compensate; that is, they hyperfunction. The cornerstone of this hypothesis is that glomerulotubular balance is maintained, such that those nephrons capable of functioning will continue to perform in an appropriate fashion. Extensive studies have shown that single-nephron GFR increases in the unaffected nephrons; thus, the whole-kidney GFR, which represents the sum of the single-nephron GFRs of the remaining functional nephrons, may remain close to normal until there is extensive injury. Based on this, we would presume that a measure of one component of nephron function could be used as an estimate of all renal functions. This, indeed, has been and remains our clinical approach.

Filtration Capacity

GFR is dependent on numerous factors, one of which is protein load. Bosch suggested that an appropriate comprehensive evaluation of renal function should include the measurement of “filtration capacity” of the kidney. This is similar in context to a cardiac stress test. The patient may have no hypoxic symptoms, for example, angina while resting, but it may become quite evident when the patient begins to exercise. Subjects with normal renal function administered an oral or IV protein load prior to measurement of GFR have been noted to increase their GFR by as much as 50%. As renal function declines, the kidneys usually compensate by increasing the single-nephron GFR. The renal reserve, the maximal degree by which GFR can be increased, will be reduced in those individuals whose kidneys are already functioning at higher than normal levels because of preexisting renal injury. Thus, this may be a complementary, insightful index of renal function reserve for many individuals with as yet unidentified CKD.

ENDOCRINE FUNCTION

The kidney synthesizes and secretes many hormones involved in maintaining fluid and electrolyte homeostasis. Secretion of renin by the cells of the juxtaglomerular apparatus and production and metabolism of prostaglandins and kinins are among the kidney’s endocrine functions. In addition, in response to decreased oxygen tension in the blood, which is sensed by the kidney, erythropoietin is produced and secreted by peritubular fibroblasts. Because these functions are related to renal mass, decreased endocrine activity is associated with the loss of viable kidney cells. In the presence of stages 3 to 5 CKD and moderate to severe acute renal injuries, secretion of erythropoietin is impaired, leading to reduced red blood cell formation; normocytic anemia, and symptoms of reduced oxygen delivery to tissues, such as fatigue, dyspnea, and angina (see Chapters 52 and 53). Renal anemia is clearly associated with as yet unidentified CKD. Indeed, anemia-induced renal hypoxia results indirectly in erythropoietin gene activation, tubular necrosis, and apoptosis, thereby contributing to further renal cell injury. This cyclic relationship between kidney disease, suppression of erythropoietin secretion, and cardiovascular disease is also referred to as the cardiorenal anemia syndrome.

METABOLIC FUNCTION

The kidneys perform a variety of metabolic functions, including the activation of vitamin D₃, gluconeogenesis, and metabolism of endogenous compounds such as insulin, steroids, and xenobiotics. Impaired renal function results in decreased formation of activated vitamin D₃ and decreased insulin metabolism. It is common for patients with diabetes and chronic renal failure to have reduced requirements for exogenous insulin, and supplemental therapy with activated vitamin D₃ (calcitriol) or other vitamin D analogues (paricalcitol and doxercalciferol) is often necessary to avert the bone loss and pain associated with renal osteodystrophy.

P450 (CYP), N-acetyltransferase, glutathione transferase, renal peptidases, and other enzymes responsible for the degradation and activation of selected endogenous and exogenous substances have been identified in the kidney. The CYP enzymes in the kidneys are as active as that in the liver, when corrected for organ mass. In vitro studies have demonstrated impaired function of CYP3A4 and CYP2C9, whereas CYP1A2, CYP2C19, and CYP2D6 are not affected. These data are supported by recent clinical trials in patients with ESRD receiving hemodialysis, where hepatic CYP3A activity was reported to be reduced by 28% from values observed in age-matched controls; partial correction was noted following the hemodialysis procedure. See Chapter 57 for a more detailed discussion.

QUALITATIVE AND SEMIQUANTITATIVE INDICES OF KIDNEY FUNCTION

Patients who develop CKD remain relatively asymptomatic until impairment has progressed to the point that systemic manifestations and/or secondary complications become evident (Table 50-2). As renal function declines, patients may develop de novo or experience an exacerbation of hypertension, edema, electrolyte abnormalities, anemia, or other complications (see Chapters 52 and 53). The National Kidney Foundation (NKF) currently recommends that all patients with CKD, and those at increased risk for CKD, undergo at least yearly a comprehensive laboratory assessment composed of (a) serum creatinine to estimate GFR; (b) albumin-to-creatinine ratio in a spot urine specimen; (c) examination of urine sediment for red blood cell and white blood cell counts; (d) renal ultrasonography; (e) serum electrolytes, including sodium, potassium, chloride, and bicarbonate; (f) urine pH; and (g) urine-specific gravity. The roles of each of these indices in the identification and monitoring of CKD are discussed in detail below.

LABORATORY PROCEDURES TO DETECT THE PRESENCE OF KIDNEY DISEASE

Urinalysis is an important tool for detecting and differentiating various aspects of kidney disease, which often goes unnoticed as the result of its asymptomatic presentation. It can be used to detect and monitor the progression of diseases such as diabetes mellitus, glomerulonephritis, and chronic urinary tract infections. A typical urinalysis provides information about physical and chemical composition, most of which can be completed quickly and inexpensively by visual observation (volume and color) and dipstick testing. Microscopic urinalysis requires use of a light microscope to determine cellular content, as described below.

Chemical Analysis of Urine

pH The normal urine pH typically ranges from 4.5 to 7.8; an elevation above this may suggest the presence of urea-splitting bacteria. In patients with renal tubular acidosis, urine pH is usually >5.5 because of impaired hydrogen ion secretion in the distal tubule or collecting duct.

Glucose Glucose is usually not present in the urine because the kidney normally completely reabsorbs all the glucose filtered at the glomerulus. When a patient’s blood glucose concentration exceeds the maximum threshold for glucose reabsorption in the kidney (~180 mg/dL [~10 mmol/L]), glucosuria will be present. Routine assessment of glucosuria has been replaced by newer methods of direct blood glucose measurements. Urine glucose testing is now used mainly as a screening tool for the detection of diabetes.

Ketones Acetoacetate and acetone normally are not found in the urine; they are, however, excreted in patients with diabetic ketoacidosis. They are also present under conditions of fasting or starvation. Typically, values of acetone excretion are reported as small (<20 mg/dL [<3.4 mmol/L]), moderate (30–40 mg/dL [5.2–6.9 mmol/L]), and large (>80 mg/dL [>13.8 mmol/L]).

Nitrite Nitrite is usually not present in urine. The presence of nitrite is most commonly the result of conversion from urinary nitrate by bacteria in the urine. The presence of nitrite thus suggests that the patient has a urinary tract infection, commonly caused by gram-negative rods such as Escherichia coli. Although false-positive results are very rare, false-negative results are more common and may be caused by a lack of dietary nitrate, reduced urine nitrate concentration as a consequence of diuresis, or infections caused by bacteria, such as enterococci and Acinetobacter, which do not reduce nitrate, and pseudomonads, which convert nitrate to nitrogen gas.

Leukocyte Esterase Leukocyte esterase is released from lysed granulocytes in the urine; its presence is suggestive of urinary tract infection. False-positive tests can result from delayed processing of the urine sample, contamination of the sample with vaginal secretions (e.g., blood or heavy mucus discharge), or by Trichomonas infection (e.g., trichomoniasis). False-negative tests can be produced by the presence of high levels of protein or ascorbic acid.

Heme The heme test indicates the presence of hemoglobin or myoglobin in the urine. A positive test without the presence of red blood cells suggests either red cell hemolysis or rhabdomyolysis.

Protein or Albumin Persistent proteinuria or albuminuria, that is, observation of its presence on at least three occasions over a period of 3 to 6 months, is now considered the principal marker of kidney damage. Evaluation of urinary protein or albumin is now a standard tool used to characterize the severity of CKD and to monitor the rate of disease progression or regression. Under normal conditions, plasma proteins remain in the glomerular capillaries as blood perfuses the kidney and thus do not cross the glomerular basement membrane or enter the urinary space. Some of these proteins, such as albumin and globulins, are not filtered by the glomerulus as a result of charge and size selectivity (>40 kDa). Smaller proteins (<20 kDa) pass across the glomerular basement membrane but are readily reabsorbed in the proximal tubule. Most healthy individuals excrete between 30 and 150 mg/day of total protein consisting of approximately 30 mg of albumin. The remainder of the protein in the urine is secreted by the
albumin per gram of creatinine (3.4–22.6 mg of albumin per millimoles) obtained from an untimed (spot) urine specimen. The normal ratio is <30 mg albumin or <200 mg protein per gram of creatinine. However, this method requires a high degree of patient compliance and is being replaced by a similarly unique crystalline form, which permits them to be identified with microscopy.

**Specific Gravity** Specific gravity is a measure of urine weight relative to water (1.00) that is performed using a refractometer. Thus, specific gravity is dependent on water intake and urine-concentrating ability. Normal values range from 1.003 to 1.030. Osmolality, which is a measure of the number of solute particles in the urine, is a more accurate measure of the kidney’s ability to make a concentrated urine. Generally, the two values correlate; however, when large quantities of heavier molecules, such as glucose, are in the urine, the specific gravity may be elevated relative to the osmolality. These tests are used in the assessment of urine-concentrating ability and are most informative when interpreted along with the hydration status of the patient and plasma osmolality.

**Microscopic Analysis of Urine** Formed elements that may be detected in the urine include erythrocytes and leukocytes, casts, and crystals. An important consideration in the assessment of hematuria is whether the cells are of renal origin. More than two cells per high-power field is abnormal, and the presence of dysmorphic cells suggests renal parenchymal origin because of damage as they pass through the glomerulus or during exposure to the varying osmotic environments of the tubular lumen. White blood cells may be present in the urine in association with infection or inflammatory conditions, such as interstitial nephritis. More than one cell per high-power field is usually considered abnormal. Contamination of the sample should also be considered, and sample collection for casts should occur with the first morning void when the urine is most acidic. Otherwise, casts may dissolve and elude detection.

A variety of crystals may be present in the urine, including uric acid, calcium oxalate, calcium phosphate, calcium magnesium ammonium pyrophosphate, and cystine. Many of these have a unique crystalline form, which permits them to be identified with microscopy.

**Serum or Blood Urea Nitrogen** Amino acids metabolized to ammonia are subsequently converted in the liver to urea, the production of which is dependent on protein availability (diet) and hepatic function. Urea undergoes glomerular filtration followed by reabsorption of up to 50% of the filtered load in the proximal tubule. The reabsorption rate of urea is mainly dependent on the reabsorption of water. The excretion of urea may therefore be decreased under conditions that necessitate water conservation, such as dehydration, although the GFR may be normal or only slightly reduced. This condition is evident when a patient exhibits prerenal azotemia, or an increase of the blood urea nitrogen to a greater extent than the serum creatinine. The normal blood urea nitrogen (BUN)-to-creatinine ratio is 10 to 15:1 using conventional units (1:25 to 1:16 using SI units), and an elevated ratio (decreased ratio using SI units) is suggestive of a decreased effective circulating volume, which stimulates increased water and hence urea reabsorption. Creatinine is not reabsorbed to any significant extent by the kidneys. Despite these limitations, BUN is usually used in combination with the serum creatinine concentration as a simple screening test for the detection of renal dysfunction.

**Clinical Controversy**

In the past, measurement of the urinary protein excretion rate was accomplished using a 24-hour urine collection in patients who were at risk for CKD. However, many now advocate the use of an untimed “spot” urine sample with either an albumin-specific dipstick or measurement of the albumin-to-creatinine ratio.
Serum Creatinine

Creatinine is the primary standard endogenous biomarker used for the detection of kidney disease. The third National Health and Nutrition Examination Survey (NHANES III) revealed a mean serum creatinine of 0.96 mg/dL (85 μmol/L) in women and 1.16 mg/dL (103 μmol/L) in men in the United States.\textsuperscript{20} Values were lower among Mexican Americans and higher among non-Hispanic blacks. For all groups, the serum creatinine increased with age. The report also noted that among community-dwelling adults, 10.9 million have a serum creatinine greater than 1.5 mg/dL (133 μmol/L), 3 million have a serum creatinine greater than 1.7 mg/dL (150 μmol/L), and 0.8 million have a serum creatinine greater than 2 mg/dL (177 μmol/L). Although the serum creatinine concentration alone is not an optimal measure of kidney function, it is often used as a marker for referral to a nephrologist. There is presently no accepted single standard for an “abnormal” serum creatinine level, as it is dependent on gender, race, age, and lean body mass.

The concentration of creatinine in serum is a function of creatinine production and renal excretion. Creatinine is a product of creatine metabolism from muscle; therefore, its production is directly dependent on muscle mass. At steady state, the “normal” serum creatinine concentration range is 0.5 to 1.5 mg/dL (44–133 μmol/L) for men and women. Creatinine is eliminated primarily by glomerular filtration, and as GFR declines, the serum creatinine concentration rises (Fig. 50–2).

Several methods are used to determine serum creatinine concentration, most of which use the nonspecific Jaffe reaction, a colorimetric method based on the reaction of creatinine with alkaline picrate. This nonspecific method also reacts with noncreatinine chromogens in the serum, which may result in a falsely increased creatinine level. The degree of interference is dependent on the clinical setting and require the clinician to be aware of the methods employed in the laboratory for the determination of creatinine concentration.

FIGURE 50-2. Relationship between serum creatinine and creatinine clearance.

clearance would underestimate the true GFR by 10%. In subjects with normal renal function, this tends to counterbalance the effect of the contribution of tubular secretion of creatinine, which increases urine creatinine by nearly 10%. Thus, CL\textsubscript{cr} has been proposed to serve as a good measure of GFR in subjects with normal renal function. However, this false increase in serum creatinine becomes less noticeable as the true creatinine concentration rises, due to the increasing contribution of tubular secretion to the renal clearance of creatinine.\textsuperscript{21} This becomes significant when kidney function is reduced to less than 50% of normal.

Diabetic ketoacidosis may produce increased concentrations of acetocetate, which serves as a chromophore in the Jaffe reaction, thereby increasing the serum creatinine concentration. Other substances that react with this procedure in the serum are glucose, protein, pyruvate, fructose, uric acid, and ascorbic acid (Table 50–3). In addition, some antibiotics are associated with a false increase in serum creatinine concentration, including cephalexin, cefazolin, ceftaxim, cefaclor, cephradine, and clavulanic acid.\textsuperscript{22,23} Other agents, such as the fluoroquinolones (ciprofloxacin, fleroxacin, lomefloxacin, ofloxacin, levofloxacin, sparfloxacin, and temafloxacin), do not produce a false elevation in serum creatinine.\textsuperscript{24} The degree of interference is dependent on the serum concentration of the antibiotic, so blood samples for creatinine should be obtained when the antibiotic concentration is lowest (at the end of a dosing interval). These interferences are not observed when the serum creatinine is measured using an enzymatic technique. The antifungal agent 5-flucytosine causes an increase in serum creatinine when measured using the Ektachem (Eastman Kodak) enzymatic system, but it does not interact with the Jaffe method.\textsuperscript{25} Daly et al.\textsuperscript{26} reported a false-negative effect of dobutamine and dopamine on the serum creatinine value when measured using the Ektachem system. The interference is concentration dependent and results in a 10% to 100% decrease in serum creatinine concentration. The authors hypothesized that both drugs compete with the chromogenic dye for oxidation by hydrogen peroxide in a concentration-dependent manner. The problem is most evident when blood samples are contaminated with residual IV solution containing the interfering drug. These differences emphasize the need to standardize a method within the clinic setting and require the clinician to be aware of the methods employed in the laboratory for the determination of creatinine concentrations.

Other compounds are known to interfere with serum creatinine concentration by inhibiting the active tubular secretion of creatinine. Among these are cimetidine and trimethoprim, which compete for creatinine secretion at the cationic transport system in a dose-dependent fashion. Cimetidine, given as a single 400 mg
dose, can result in a reduction of the CLcr-to-inulin clearance ratio from 1.30 to 1.03, without a change in insulin clearance. Ranitidine, an H2-receptor antagonist similar to cimetidine, however, does not have a similar effect on creatinine secretion following single doses of 300 to 1,200 mg.27

Serum creatinine concentration is dependent on the “input” function, or formation rate, and “output” function, or elimination rate. Its formation rate depends on the zero-order production from creatine metabolism, as well as input from other sources, such as dietary intake. Creatine metabolism is directly proportional to muscle mass; therefore, individuals with more muscle mass have a higher serum creatinine concentration at any given degree of kidney function than those with less muscle mass. Strenuous exercise is associated with an increase of ~10% in the level of serum creatinine. In contrast, cachectic patients, as the result of minimal muscle mass, will have very low serum creatinine concentrations, as do those with spinal cord injuries.28 Elderly patients and those with poor nutrition may also have low serum creatinine concentrations (<1.0 mg/dL [88 μmol/L]) secondary to decreased muscle mass. Dietary intake of creatine also influences serum creatinine concentration. During the cooking of meat, some creatine is converted to creatinine, which is rapidly absorbed following ingestion.

Serum creatinine concentrations may rise as much as 50% within 2 hours of a meat meal and remain elevated for as long as 8 to 24 hours.29 Ingestion of creatine as an ergogenic dietary supplement is currently popular. There are conflicting reports as to the effect of creatine ingestion on serum creatinine concentration. Poortmans and Francaux30 evaluated a short-term regimen of 20 g creatine per day for 5 days in healthy subjects and reported no significant change in serum creatinine concentration, creatinine excretion rate, or creatinine clearance. Robinson et al.,31 however, reported a 25% to 40% increase in serum creatinine concentration after ingestion of 20 g creatine per day for either 5 days or 8 weeks. The renal excretion rate of creatinine was not measured. The issue of whether creatine ingestion adversely affects kidney function was studied by Edmunds et al.32 They noted that creatine supplementation led to an increase in renal disease progression in a rat model for renal cystic disease, suggesting that creatine supplementation may be a risk factor in patients with preexisting renal disease. These conditions present a problem only when a single serum creatinine concentration is used to represent the entire 24-hour collection period, which is usually the case. An alternative is to obtain multiple samples and calculate the area under the serum concentration time curve and divide this by the collection time interval to obtain the average plasma creatinine concentration. This is rarely done in clinical practice, but it points out the need to question patients regarding dietary intake for the 24 hours preceding the measurement of CLcr.

Diurnal variation in serum creatinine concentration may also affect the accuracy of the CLcr determination. Although the fluctuation is minimal, the observed peak plasma creatinine concentration generally occurs at approximately 7:00 PM, whereas the nadir is in the morning. To minimize this effect, the CLcr is usually performed over a 24-hour period with the plasma creatinine obtained in the morning, as long as the patient has stable kidney function. Collection of urine remains a limiting factor in the 24-hour CLcr because of incomplete collections and interconversion between creatinine and creatine that can occur if the urine is not maintained at a pH <6.

**Serum and Urinary Cystatin C**

Cystatin C is a 132 amino acid (13.3 kDa) cysteine protease inhibitor produced by all nucleated cells of the body that is considered a biomarker of renal function. It is freely filtered at the glomerulus and undergoes both reabsorption and catabolism in the proximal tubule. The renal handling of this biomarker is distinctly different from creatinine and exogenous GFR markers, such as inulin, iohekol, and iothalamate. Originally introduced in Europe, it was recommended as a marker of kidney function because of findings that serum concentrations significantly correlated with GFR as well as serum creatinine. It was hypothesized that because cystatin C production was not limited to muscle mass, it would provide a more reliable estimate of renal function than creatinine. However, it has now been shown that serum cystatin C concentrations can be altered by many factors other than kidney function, such as age, nutritional status, gender, weight, height, cigarette smoking, serum C-reactive protein levels, steroid therapy, and rheumatoid arthritis.33-35 Recent studies have reported that it may be a more sensitive index of kidney disease or acute injury compared with serum creatinine. Comparison of 125I-iothalamate with serum creatinine and cystatin C showed that the serum creatinine began to increase when the GFR was <75 mL/min/1.73 m2 (0.72 mL/s/m2), whereas cystatin C concentrations began to rise when the GFR dropped below 88 mL/min/1.73 m2 (0.85 mL/s/m2).36 The recent development of an automated immunoassay technique has resulted in the development of suggested reference ranges of 0.70 to 1.38 mg/L in children older than 1 year of age and 0.55 to 1.37 mg/L in adults. However, Keevil et al.37 reported that serum cystatin C had greater intra-individual variability than serum creatinine in healthy individuals, which may limit its use in longitudinal evaluations of renal function.

The utility of cystatin C as a quantitative measure of GFR is still largely unknown. In a 4-year longitudinal study in 30 Pima Indians without CKD, the reciprocal cystatin C index (100/cystatin C) was shown to be a better predictor of declining GFR than was reciprocal serum creatinine, estimated GFR, or CLcr.37 However, in patients being treated for malignant disease, Page et al.38 reported increased cystatin C concentrations that were independent of CLcr. Cystatin C concentrations were also noted to be independent of GFR and weakly associated with measured creatinine clearance, in pediatric and adult renal transplant recipients, possibly due to the formation of cystatin-immunoglobulin complexes or reduced tubular catabolism.39,40 Two additional studies have shown a strong association between serum cystatin C and cardiovascular disease in elderly and non-CKD patients, suggesting that it may provide useful prognostic information in some populations.41,42

In addition to longitudinal monitoring of serum cystatin C values, at least five equations have been proposed to determine estimated GFR (eGFR) using serum cystatin C (CysC) and demographic variables including lean body mass (LM), age, gender, race, and serum creatinine (Scr).43-46

\[
eGFR (\text{mL/min}) = 77.24 \times (\text{CysC in mg/L})^{-1.2623}
\]

\[
\log_{10}eGFR (\text{mL/min}) = 2.222 + \left( -0.802 \times \sqrt{\text{CysC in mg/L}} \right) + (0.009876 \times \text{LM})
\]

\[
eGFR (\text{mL/min/1.73 m}^2) = 127.7 \times (\text{CysC in mg/L})^{-1.17} \times (\text{age in years})^{-0.13} \times 0.91 \times 1.06 \ [\text{if female}] \times 1.16 \ [\text{if black}]
\]

\[
eGFR (\text{mL/min/1.73 m}^2) = 76.7 \times (\text{CysC in mg/L})^{-1.19} \times (\text{CysC in mg/L})^{-0.57} \times (\text{age in years})^{-0.20} \times 0.82 \ [\text{if female}] \times 1.11 \ [\text{if black}]
\]

Conversion from eGFR conventional units of mL/min/1.73 m2 to eGFR SI units of mL/s/m2 requires multiplication by 0.00963; conversion from eGFR conventional units of mL/min to eGFR SI units of mL/s requires multiplication by 0.0167. Serum creatinine in μmol/L can be converted to mg/dL by multiplication using 0.0113 as the conversion factor.
Recent studies by MacDonald et al.\textsuperscript{43} and Vupputuri et al.\textsuperscript{46} reported that body weight is a significant covariate in GFR determination using cystatin C. Using GFR measured as plasma inulin clearance, lean body mass accounted for at least 16.3% of the variance in GFR values obtained using cystatin C ($P < 0.001$). When using a cystatin C-based estimate of GFR, which incorporates the CySC, age, race, and gender, a higher prevalence of CKD was reported in obese patients when compared with the MDRD4 equation.\textsuperscript{46} Thus, a rigorous evaluation of the impact of body composition and obesity on GFR estimates using cystatin C is needed.

**Alternative Methodologies**

Urinary biomarkers such as KIM-1, NGAL, and cystatin C have shown promise in detecting early kidney injury.\textsuperscript{41} Because it is normally reabsorbed and catabolized in the renal proximal tubule, it is hypothesized that tubular damage would lead to increased urinary excretion of cystatin C. Koyner et al.\textsuperscript{48} showed that postoperative cardiac surgery patients with early elevated urinary cystatin C concentrations (corrected for urinary creatinine) had the highest prevalence of developing acute kidney injury (AKI). Here, plasma creatinine concentrations did not peak until 48 hours after admission to the intensive care unit, suggesting that urinary biomarkers such as cystatin C may be beneficial in early diagnosis of AKI. Use of cystatin C as a quantitative measure of GFR requires further study and may yield useful information for comprehensive evaluations of health and cardiovascular status, including detection of acute and chronic changes in kidney function.

Beta-trace protein (BTP) has recently been proposed as a new alternate endogenous marker of GFR.\textsuperscript{49-51} Similar to cystatin C, it is a low molecular weight glycoprotein (168 amino acids) that is filtered through the glomerular basement membrane and reabsorbed in the renal proximal tubule. Elevated concentrations of BTP in serum have been reported in patients with CKD,\textsuperscript{52} kidney transplant recipients,\textsuperscript{53} and children.\textsuperscript{54} Equations to estimate GFR that incorporate BTP concentrations in adults and pediatric populations are currently being evaluated.\textsuperscript{55}

### MEASUREMENT OF KIDNEY FUNCTION

The gold standard quantitative index of kidney function is a measured GFR. A variety of methods may be used to measure and estimate kidney function in the acute care and ambulatory settings. Estimation of GFR is important for early recognition and monitoring of patients with CKD. Estimation of CL, is important as a guide for drug dose adjustment in the presence of renal impairment.

It is important to recognize conditions that may alter renal function independent of underlying renal pathology. For example, protein intake, such as oral protein loading or an infusion of amino acid solution, may increase GFR.\textsuperscript{56} As a result, inter- and intrasubject variability must be considered when it is used as a longitudinal marker of renal function. Dietary protein intake has been demonstrated to correlate with GFR in healthy subjects. Brändle et al.\textsuperscript{56} evaluated renal function in four groups of healthy volunteers, each ingesting a diet controlled for protein over a 4-month period. The GFR was nonlinearly related to urine nitrogen excretion, with an observed maximum of 181.7 mL/min (3.03 mL/s) at a urinary nitrogen excretion rate of 20 g/day (1.43 mol/d, or 125 g/day protein intake). Subjects who are vegetarian have a lower GFR than individuals who consume a similar caloric but normal protein content diet because of their reduced dietary protein intake. When challenged with a protein load, the vegetarian subjects are able to increase their GFR to the “normal” range.\textsuperscript{57} Findings from the Nurses’ Health Study\textsuperscript{58} indicate that longitudinal changes in GFR are independent of the source of protein (nondairy animal, dairy, or vegetable) in women with normal renal function. However, women with mild renal insufficiency (GFR 71 ± 7 mL/min [1.18 ± 0.12 mL/s]) who consumed the highest amount of protein (93 g/day) had a threefold greater risk of a ≥5 mL/min (≥0.08 mL/s) decline in GFR compared with the lowest protein group (60 g/day); rates of decline were highest in those consuming nondairy animal protein. The increased GFR following a protein load is the result of renal vasodilation accompanied by an increased renal plasma flow. The exact mechanism of the renal response to protein is unknown but may be related to extrarenal factors such as glucagon, prostaglandins, and angiotensin II, or to intrarenal mechanisms, such as tubular transport and tubuloglomerular feedback.\textsuperscript{59,60} Despite the evidence of a “renal reserve,” standardized evaluation techniques have not been developed. Therefore, assessment of the standard GFR measurement technique must consider the dietary protein status of the patient at the time of the study.

### MEASUREMENT OF THE GLOMERULAR FILTRATION RATE

A measured GFR remains the single best index of functioning renal mass. As renal mass declines in the presence of age-related loss of nephrons or coexisting disease states such as hypertension and diabetes, there is a progressive decline in GFR. The rate of decline in GFR can be used to predict the time to onset of stage 5 CKD, as well as the risk of complications of CKD. Accurate measurement of GFR in clinical practice is a critical variable for the individualization of the dosage regimens of renally excreted medications so as to maximize their therapeutic efficacy and avoid potential toxicity.

The GFR is expressed as the volume of plasma filtered across the glomerulus per unit time, based on total renal blood flow and capillary hemodynamics. The normal values for GFR are 127 ± 20 mL/min/1.73 m$^2$ (1.22 ± 0.19 mL/s/m$^2$) and 118 ± 20 mL/min/1.73 m$^2$ (1.14 ± 0.19 mL/s/m$^2$) in healthy men and women, respectively. For example, if the normal renal blood flow was ~1 L/min/1.73 m$^2$ (0.01 mL/s/m$^2$), plasma volume was 60% of blood volume, and filtration fraction across the glomerulus was 20%, then the normal GFR would be ~120 mL/min/1.73 m$^2$ (1.16 mL/s/m$^2$).

Because GFR cannot be measured directly in humans, clearance methods that use substances that are freely filtered without additional clearance because of tubular secretion or reduction as the result of reabsorption are required. Additionally, the substance should not be susceptible to metabolism within renal tissues and should not alter renal function. Given these conditions, the GFR is equivalent to the renal clearance of the solute marker:

$$\text{GFR} = \text{renal CL} = \frac{A_e}{AUC_{0-t}}$$

where renal CL is renal clearance of the marker, $A_e$ is the amount of marker excreted in the urine in a specified period of time, $t$, and $AUC_{0-t}$ is the area under the plasma concentration-versus-time curve of the marker.

Under steady-state conditions, for example, during a continuous infusion of the marker, the expression simplifies to

\[
GFR = \frac{CL}{c_{ss}} = \frac{dose}{AUC}
\]

where \(c_{ss}\) is the steady-state plasma concentration of the marker achieved during continuous infusion. The continuous infusion method can also be employed without urine collection, where plasma clearance is calculated as \(CL = \text{infusion rate}/c_{ss}\). Requirements of this method include steady-state plasma concentrations and accurate measurement of infused concentrations. Plasma clearance can also be determined following a single-dose IV injection with multiple samplings of blood to estimate area under the curve (AUC). Here, clearance is calculated as \(CL = dose/AUC\). These plasma clearance methods commonly yield clearance values 10% to 15% higher than urine collection methods.60,61 Several markers have been used for the measurement of GFR, including both exogenous and endogenous compounds. Those administered as exogenous agents, such as inulin, iothalamate, iohexol, and radioisotopes, require specialized administration techniques and detection methods for the quantification of function, but they generally provide a more accurate measure of GFR. Methods that employ endogenous compounds, such as creatinine, require less technical expertise but produce results with greater variability. The marker of choice depends on the purpose and cost of the test (e.g., 125I-iothalamate costs $2,000 per vial [Glofill-125, QOL Medical]; research protocols will generally use a more accurate test than one used in the clinical setting (Table 50–4).

**Inulin Clearance**

Inulin is a large fructose polysaccharide (5,200 Da) obtained from the Jerusalem artichoke, dahlia, and chicory plants. It is not bound to plasma proteins, is freely filtered at the glomerulus, is not secreted or reabsorbed, and is not metabolized by the kidney. The volume of distribution of inulin approximates extracellular volume, or 20% of ideal body weight. Because it is eliminated by glomerular filtration, its elimination half-life is dependent on renal function and is ~1.3 hours in subjects with normal renal function. Measurement of plasma and urine inulin concentrations can be performed using high-performance liquid chromatography.62 Sinistrin, another polyfructosan, has similar characteristics to inulin; it is filtered at the glomerulus and not secreted or reabsorbed to any significant extent. It is a naturally occurring substance derived from the root of the North African vegetable red squill, *Urginea maritima*, which has a much higher degree of water solubility than inulin. Assay methods for sinistrin have been described using enzymatic procedures, as well as high-performance liquid chromatography with electrochemical detection.63

**Iothalamate Clearance**

Alternatives have been sought for inulin as a marker for GFR because of the problems of availability, high cost, sample preparation, and assay variability. Iothalamate is an iodine-containing radiocontrast agent that is available in both radiolabeled (125I) and nonradiolabeled forms. This agent is handled in a manner similar to that of inulin; it is freely filtered at the glomerulus and does not undergo substantial tubular secretion or reabsorption. The nonradiolabeled form is most widely used to measure GFR in ambulatory and research settings and can safely be administered by IV bolus, continuous infusion, or subcutaneous injection.64 Plasma and urine iothalamate concentrations can be measured using high-performance liquid chromatography.64 A reported slight positive bias of ~10 mL/min (0.17 mL/s) suggests that there is some degree of nonrenal clearance of this agent. However, plasma iothalamate clearance methods that do not require urine collections have been shown to be highly correlated with iothalamate renal clearance, making them particularly well suited for longitudinal evaluations of renal function.66

**Iohexol**

Iohexol, a nonionic, low osmolar, iodinated contrast agent, has also been used for the determination of GFR. It is eliminated almost entirely by glomerular filtration, and plasma and renal clearance values are similar to observations with other marker agents: strong correlations of 0.90 or greater and significant relationships such as \(CL_{\text{iohexol}} = 0.90 CL_{\text{iothalamate}} + 6.8\ mL/min\) have been reported.67–69 These data support iohexol as a suitable alternative marker for the measurement of GFR. One key advantage of this agent is that a single plasma sample can be used to quantify iohexol clearance, provided sufficient time has elapsed since injection. For patients with a reduced GFR, more time must be allotted—more than 24 hours if the estimated GFR is less than 20 mL/min (0.33 mL/s).67

**Radiolabeled Markers**

The GFR has also been quantified using radiolabeled markers, such as 125I-iothalamate (614 Da, radioactive half-life of 60 days), 99mTc-diethylenetriamine pentaacetic acid (99mTc-DPTA; 393 Da, radioactive half-life of 6.03 hours), and 51Cr-ethylenediaminetetraacetic acid (51Cr-EDTA; 292 Da, radioactive half-life of 27 days).70 These relatively small molecules are minimally bound to plasma proteins and do not undergo tubular secretion or reabsorption to any significant degree.125I-iothalamate and 99mTc-DPTA are used in the United States, whereas 51Cr-EDTA is used extensively in Europe. The use of radiolabeled markers allows one to determine the individual contribution of each kidney to total renal function.71 Various protocols exist for the administration of these markers and subsequent determination of GFR using either plasma or renal clearance calculation methods. The nonrenal clearance of these agents appears to be low (3–8 mL/min [0.05–0.13 mL/s]), suggesting that plasma clearance is an acceptable technique except in patients with severe renal insufficiency (GFR <30 mL/min [<0.50 mL/s]). Indeed, highly significant correlations between renal clearance among radiolabeled markers has been demonstrated.72 Although total radioactive exposure to patients is usually minimal, use of one of these agents does require compliance with radiation safety committees and appropriate biohazard waste disposal.

**Estimation of GFR**

A series of equations for estimating GFR have been proposed over the past 10 years (Table 50–5). The most commonly used equations are those proposed by Levey and colleagues,73–77 which have gained widespread support for the estimation of GFR as a tool for the identification and risk categorization of CKD in many patient populations. The initial equations were derived from multiple regression analysis of data obtained from the 1,628 patients enrolled in the Modification of Diet in Renal Disease Study (MDRD), where GFR was measured by renal clearance of 125I-iothalamate. The first regression model yielded
a six-variable Modification of Diet in Renal Disease Study (MDRD6) equation. This new equation had a higher correlation coefficient ($r^2 = 0.902$) and thus provided a more precise estimate of GFR than measured $Cl_{\text{Cr}}$ using $ABW$, $S_{\text{cr}}$, age, and gender as the covariates. The MDRD6 equation is now recommended by the NKF and the National Kidney Disease Education Program (NKDEP) for calculating the estimated GFR (eGFR) in patients with a history of CKD risk factors and a GFR <60 mL/min/1.73 m$^2$ (<0.58 mL/s/m$^2$). The performance of the MDRD6 equation has been assessed in a variety of patient populations with GFR <60 mL/min/1.73 m$^2$ (<0.58 mL/s/m$^2$), including those with diabetic nephropathy and renal transplant patients. However, the MDRD4 equations have been shown to be less accurate in healthy subjects, diabetic patients with normal GFR (88–182 mL/min/1.73 m$^2$ [0.85–1.75 mL/s/m$^2$]), and healthy, stable kidney donors. In a small study of elderly subjects (age >68 years) with mild/moderate CKD (GFR 53 ± 18 mL/min/1.73 m$^2$ [0.51 ± 0.17 mL/s/m$^2$]), the MDRD6 equation was slightly positively biased compared with the Cockcroft-Gault equation (8% vs. 10%), but precision was similar between methods relative to measured GFR.

Beddhu et al. reported that the MDRD6 equation, like the Cockcroft-Gault equation, is dependent on creatinine production and is susceptible to bias in malnourished patients with ESRD. In patients with GFR values >60 mL/min/1.73 m$^2$ (>0.58 mL/s/m$^2$), the values provided by the MDRD6 equation have been shown to be highly variable and less accurate than other traditional estimation methods, perhaps in part because the original study population consisted only of patients with low GFR values (<60 mL/min/1.73 m$^2$ [0.58 mL/s/m$^2$]). The study also included few Asians, elderly patients, those with diabetes, or ill, hospitalized patients; thus, the MDRD4 should be used with caution in children, the elderly, and those with extremes in muscle mass (cachectic and obese) until further performance data are available.

### CLINICAL CONTROVERSY

Some practitioners are advocating the use of the MDRD4 equation in patients without CKD, although it appears to have a weaker correlation with GFR than the Cockcroft-Gault equation. Recent evidence suggests that the MDRD4 equation should be reserved for patients with a GFR <60 mL/min. The use of newer equations, such as the CKD-EPI, may have improved accuracy in patients with GFR >60 mL/min; however, further studies are required.

A single GFR equation may not be best suited for all populations, and choice of equation has been shown to affect CKD prevalence estimates. This has led to a revitalized interest in the areas of nephrology, epidemiology, and development of new GFR equations over the past 5 years. The newest equations to be proposed for the estimation of GFR have been derived from wider CKD populations than the MDRD study and include the CKD-EPI and Mayo Clinic Quadratic (MCQ) equations. The CKD-EPI equation was developed from pooled study data involving 5,500 patients, with mean GFR values of 68 ± 40 mL/min/1.73 m$^2$ (0.65 ± 0.39 mL/s/m$^2$) (range 2–190 mL/min/1.73 m$^2$ [0.02–1.83 mL/s/m$^2$]). It has been reported that the CKD-EPI equation is less biased (2.5 vs. 5.5 mL/min/1.73 m$^2$ [0.024 vs. 0.053 mL/s/m$^2$]) but similarly imprecise compared with MDRD4. Rule et al. developed the MCQ equation to estimate GFR from a population of CKD ($n = 320$) and healthy individuals ($n = 580$), using $1/S_{\text{cr}}, 1/S_{\text{cr}}^2, \text{age}$, and gender as the covariates. Using the NHANES database, Snyder et al. reported that MCQ GFR values resulted in 28% fewer patients being categorized as CKD stage 3 or 4 when compared with MDRD4. Thus, further evaluation of these newer GFR equations, including those incorporating “correction factors” for Japanese and Chinese populations, is needed. A variety of online resources that provide GFR calculators are available, such as the NKDEP website, which provides GFR using the MDRD4 and MDRD4-IDMS equations. It should be noted that one must verify that a given equation is appropriate for the institutional creatinine reporting method.

The approach to standardize serum creatinine assays, and thereby improve the accuracy of eGFR results, has been implemented in most hospital clinical laboratories. This IDMS assay calibration, called isotope dilution-mass spectrometry, is designed to reduce the interlaboratory variability in serum creatinine values. In settings using IDMS calibration, the revised MDRD-IDMS equation should be used based on the estimated 5% to 20% reduction in creatinine values. Recent recommendations from the NKDEP include reporting serum creatinine values in mg/dL to two decimal places (e.g., 0.93 mg/dL) and values in μmol/L to the nearest whole number (e.g., 84 μmol/L). This practice will likely reduce rounding errors that in the past contributed to bias between creatinine-based GFR or $Cl_{\text{Cr}}$ estimates, but it does not improve GFR estimation in those without CKD. The impact of this new creatinine reporting approach on the accuracy of automated GFR results, calculated by a specified method, remains to be determined.

* $ABW$ is actual body weight, $\text{Alb}$ is serum albumin concentration (g/dL), $Cl_{\text{Cr}}$ is creatinine clearance (mL/min), $GFR$ is glomerular filtration rate, $IBW$ is ideal body weight (kg), $S_{\text{Cr}}$ is serum or plasma creatinine (mg/dL), $SUN$ is serum urea nitrogen concentration (mg/dL).
Drug dose individualization is often required in patients with CKD. Approved drug labeling typically includes dose adjustment information based on the patient’s estimated Clcr using the Cockcroft-Gault method. Automated eGFR reporting by many hospital laboratories has now raised the question if the MDRD4 or any other GFR estimation equations should be used as a guide for drug dose adjustments.

Clinical Controversy

The use of ideal or lean body weight for estimating Clcr in obese patients is controversial. Some clinicians recommend using a weight adjustment in patients who are greater than 30% above IBW, such as using an adjusted body weight. However, some FDA package inserts provide renal dosing recommendations based on Clcr calculations using IBW. Further research evaluating weight-based adjustments and drug pharmacokinetic outcomes is needed.

Measured Creatinine Clearance

Although the measured (24-hour) Clcr has served as the basis of developing Clcr estimation equations in the past, it has limited clinical utility for estimation of GFR. Short-duration witnessed Clcr correlates with iothalamate clearance performed using the single-injection technique. In a multicenter study of 136 patients with type I diabetic nephropathy, the correlations of simultaneous Clcr, Cockcroft-Gault Clcr, and 24-hour Clcr (compared with Cliothalamate) were 0.81, 0.67, and 0.49, respectively, indicating increased variability with the 24-hour clearance determination. In a selected group of 110 patients, measurement of a 4-hour Clcr during water diuresis provided the best estimate of the GFR as determined by the Cliothalamate. Furthermore, the ratio of Clcr to Cliothalamate did not appear to increase as the GFR decreased. These data suggest that a short collection period with a water diuresis may be the best method for estimation of GFR by creatinine clearance.

A limitation of using creatinine as a filtration marker is that it undergoes varying degrees of tubular secretion. Tubular secretion augments the filtered creatinine by ~10% in subjects with normal kidney function. If the nonspecific Jaffe reaction is used, which overestimates the serum creatinine concentration by ~10% because of the noncreatinine chromogens, then the creatinine clearance is a very good measure of GFR in patients with normal kidney function. Tubular secretion, however, increases to as much as 100% in patients with renal insufficiency. As renal impairment develops, the remaining nephrons hypertrophy, and the degree of tubular secretion decreases less than the decrease in filtration. The result is an overestimation of creatinine clearance as a function of GFR assessed by inulin or iothalamate clearance. For example, Bauer et al. reported that the Clcr-to-Clinulin ratio, in patients with mild impairment was 1.20; for moderate impairment, it was 1.87; and for severe impairment, it was 2.32. Thus, creatinine clearance is a poor indicator of GFR in patients with moderate to severe renal insufficiency.

Because cimetidine blocks the tubular secretion of creatinine, the potential role of several oral cimetidine regimens to improve the accuracy and precision of creatinine clearance as an indicator of GFR has been evaluated. The Clcr-to-Clinulin ratio declined from 1.33 with placebo to 1.07 when 400 mg of cimetidine was administered four times daily for 2 days prior to and during the clearance determination. Similar results were observed when a single 800 mg dose of cimetidine was given 1 hour prior to the simultaneous determination of Clcr and Cliothalamate; the ratio of Clcr to Cliothalamate was reduced from a mean of 1.53 to 1.12. Thus, a single oral dose of cimetidine 800 mg should provide adequate blockade of creatinine secretion to improve the accuracy of a creatinine clearance measurement as an eGFR in patients with stages 3 to 5 CKD.

Estimation of Creatinine Clearance

Many equations describing the mathematical relationships between various patient factors and Clcr have been reported over the past 3 decades. Most equations incorporate factors such as age, gender, weight, and serum creatinine concentration, without the need for urine collection. The most widely used of these estimators is the Cockcroft-Gault equation, which identified age and body mass as factors that significantly contribute to the estimate of Clcr. This relationship was based on observations from 249 male patients with stable kidney function in whom the creatinine production rates were estimated. Estimated creatinine clearance, using the Cockcroft-Gault equation, remains the most common approach for stratifying patients in pharmacokinetic studies in clinical development and is reported most often in FDA-approved package inserts for new drug entities.

The issue of which if any modified weight index should be used in the Cockcroft-Gault equation remains controversial, and approaches vary widely among clinical practitioners. For obese individuals, defined as those weighing >30% their ideal body weight (IBW), it is generally recommended that IBW be used in place of actual body weight (ABW) in the Cockcroft-Gault equation, where

\[
\text{IBW (kg, men)} = 50 + 2.3 \text{ (height in inches >60)}
\]

\[
\text{IBW (kg, women)} = 45 + 2.3 \text{ (height in inches >60)}
\]

An alternative approach for estimating Clcr (mL/min) in obese patients is the Salazar-Corcoran equation, which has been shown to be unbiased and superior to the Cockcroft-Gault equation in this population. In the morbidly obese population, such as those with body mass index (BMI) ≥ 40 kg/m², use of lean body weight was recently reported to improve the accuracy of the Cockcroft-Gault equation in predicting 24-hour Clcr. Regardless of the approach used to estimate renal function in obese patients, it is imperative that drug therapy outcomes be monitored closely in this special population.

Clinical Controversy

The use of ideal or lean body weight for estimating Clcr in obese patients is controversial. Some clinicians recommend using a weight adjustment in patients who are greater than 30% above IBW, such as using an adjusted body weight. However, some FDA package inserts provide renal dosing recommendations based on Clcr calculations using IBW. Further research evaluating weight-based adjustments and drug pharmacokinetic outcomes is needed.

Luke et al. evaluated the ability of the Cockcroft-Gault method and four other methods to predict Clcr, with inulin clearance being considered the standard measure of GFR. The simultaneously determined inulin and creatinine clearances correlated best, \( r^2 = 0.85 \), and the Clcr overestimated Clinulin by ~15% due to tubular secretion of creatinine. For the five calculated clearances, Cockcroft-Gault and Mawer et al. correlated the best with inulin clearance. The Cockcroft-Gault method showed a linear relationship with Clinulin equal to 1.212 of Clcr plus 20.6 mL/min (0.34 mL/s) \( (r^2 = 0.66) \), whereas for Mawer et al., the relationship was Clinulin equal to 1.051 of Clcr plus 18.3 mL/min (0.31 mL/s) \( (r^2 = 0.66) \). Other methods, such as Jelliffe and Hull et al., consistently underestimated the Clcr. As kidney function declined, there was an increase in the fraction of creatinine eliminated by secretion as measured by the Clcr-to-Clinulin ratio, consistent with earlier reports. Gault et al. also evaluated the performance of the Cockcroft-Gault estimator of renal function compared with inulin and \(^{99}\text{Tc-DPTA}\). Except for conditions of unstable kidney function, it performed like the 24-hour creatinine clearance method (Table 50–5).
Patients undergoing screening for participation in the African American Study of Kidney Disease (AASK) were evaluated for kidney function based on an estimated CL\textsubscript{cr} compared with the simultaneous \textsuperscript{125}I-iothalamate and measured 24-hour CL\textsubscript{cr}.\textsuperscript{98} The simultaneous CL\textsubscript{cr} provided the best estimate of GFR. Cockcroft-Gault was the preferred method for estimation of GFR, based on performance and ease of use. This method was noted to underestimate the GFR by 9%, perhaps because of the increased excretion rate of creatinine by black patients.\textsuperscript{99,99}

Administration of cimetidine has also resulted in improved performance of the Cockcroft-Gault equation to predict GFR. Ixkes et al.\textsuperscript{100} gave patients three 800 mg doses of cimetidine in 24 hours and measured creatinine plasma levels from 3 to 7 hours following the final dose. During this 4-hour period, the CL\textsubscript{iodate} was determined as the measure of GFR. The Cockcroft-Gault calculations were performed with the plasma creatinine measurement 3 hours after the last dose of cimetidine. The ratio of the Cockcroft-Gault estimated CL\textsubscript{cr} to CL\textsubscript{iodate} ratio decreased from 1.28 ± 0.21 to 0.98 ± 0.11 in the presence of cimetidine. This cimetidine dosing schedule also improved the accuracy of Cockcroft-Gault estimates relative to GFR in renal transplant patients with GFR values ranging from 20 to 80 mL/min/1.73 m\textsuperscript{2} (0.19–0.77 mL/s/m\textsuperscript{2}).\textsuperscript{101,102}

Liver Disease

The prediction of CL\textsubscript{cr} or GFR is particularly problematic in patients with preexisting liver disease and renal impairment. Lower than expected serum creatinine values may result from reduced muscle mass, protein-poor diet, diminished hepatic synthesis of creatine (a precursor of creatinine), and fluid administration and can lead to significant overestimation of creatinine clearance. Orlando et al.\textsuperscript{103} evaluated 10 healthy subjects, 10 patients with mild liver disease, and 10 with severe liver disease and observed a measured CL\textsubscript{cr} to CL\textsubscript{inulin} ratio of 1.05, 1.03, and 1.04 for each group, respectively. When the CL\textsubscript{cr} of patients with severe liver disease was estimated using the Cockcroft-Gault equation, the resultant ratio (CL\textsubscript{cr} Cockcroft-Gault to CL\textsubscript{inulin}) was 1.23. Lam et al.\textsuperscript{104} likewise noted an overprediction by Cockcroft-Gault of the measured CL\textsubscript{cr} in patients with severe disease, by 40% to 100%.

Studies of renal function in patients with severe hepatic disease confirm the earlier observations of Hull et al.\textsuperscript{95} and Caregaro et al.\textsuperscript{105} who reported that measured CL\textsubscript{cr} overestimated GFR by 50% in hepatic patients with a GFR of 56 ± 19 mL/min/1.73 m\textsuperscript{2} (0.54 ± 0.18 mL/s/m\textsuperscript{2}) because of increased tubular secretion of creatinine. The effect of cimetidine administration on measured CL\textsubscript{cr} was recently evaluated in a small study by Sanseo et al.\textsuperscript{106} In 12 patients with compensated cirrhosis, serum creatinine values increased from 0.68 ± 0.11 to 0.94 ± 0.14 mg/dL (69 ± 10 μmol/L to 83 ± 12 μmol/L) during coadministration of cimetidine (1,000 mg given as 400 mg × 1, then 200 mg every 3 hours) during a 9-hour clearance period. The CL\textsubscript{cr} was reduced from 138 ± 20 to 89 ± 13 mL/min (2.30 ± 0.33 to 1.49 ± 0.22 mL/s), with no change in measured GFR.

DeSanto et al.\textsuperscript{107} studied 19 patients with mild liver disease whose inulin and creatinine clearances were 90 ± 4.4 and 122 ± 7 mL/min/1.73 m\textsuperscript{2} (0.87 ± 0.042 and 1.17 ± 0.067 mL/s/m\textsuperscript{2}), respectively. The degree of overestimation of GFR by creatinine clearance was inversely correlated with GFR (r = 0.452, P <0.04). In cirrhotic patients being evaluated for liver transplant (GFR 58 ± 5.1 mL/min/1.73 m\textsuperscript{2} [0.56 ± 0.049 mL/s/m\textsuperscript{2}]), the MDRD4, MDRD6, and Cockcroft-Gault equations significantly overestimated GFR by 30% to 50% and were imprecise estimates of GFR before and after liver transplantation.\textsuperscript{108,109} Thus, measurement of renal function in patients with hepatic disease should be performed using a method specific for glomerular filtration, and estimation equations for GFR or creatinine clearance should be avoided.

Other Special Populations

Davis and Chandler\textsuperscript{110} confirmed the accuracy of the Cockcroft-Gault equation to predict CL\textsubscript{cr} in trauma patients with stable kidney function, and Thakur et al.\textsuperscript{28} demonstrated its successful use in 42 paraplegic subjects. Renal transplant recipients are frequently monitored for renal function, as numerous complications may occur during the life of the allograft. Goerdts et al.\textsuperscript{111} assessed the bias and precision with which several nomographic methods predicted GFR (iohexol clearance) in 127 patients with stable kidney function. The Cockcroft-Gault method performed poorly, overestimating iohexol clearance. This is expected, as iohexol clearance provides a true measure of GFR, whereas the Cockcroft-Gault CL\textsubscript{cr} estimate is falsely high because of the tubular secretion of creatinine. Huang et al.\textsuperscript{112} reported the inability of several CL\textsubscript{cr} equations to predict renal function in hospitalized patients with advanced human immunodeficiency virus (HIV) disease. All of the prediction methods overestimated the measured 24-hour CL\textsubscript{cr}. The reasons for the poor predictability of these methods are unclear, although 24-hour collection methods result in increased variability, often because of inadequate collection of urine.

Renal function assessment during pregnancy is usually performed using a 24-hour creatinine clearance determination. Quadri et al.\textsuperscript{113} evaluated the Cockcroft-Gault method during each trimester in 34 pregnant women and compared these estimates with the measured 24-hour CL\textsubscript{cr}. Prepregnancy weights were used throughout the study for the Cockcroft-Gault method, and results correlated well with the measured clearances (r\textsuperscript{2} = 0.76). The maximal CL\textsubscript{cr} occurred during the second trimester for both methods.

Unstable Renal Function

Patients with unstable kidney function present a unique situation because serum creatinine values are changing, and steady state cannot be assumed when estimating CL\textsubscript{cr}. It can take several days for serum creatinine values to reach steady state in early acute renal failure, but this time can be reduced when renal function is improving. In patients with previously normal renal function, a change in the serum creatinine concentration >50% over a period of 1 day is suggestive of unstable renal function. In patients with preexisting CKD (GFR <60 mL/min/1.73 m\textsuperscript{2} [<0.58 mL/s/m\textsuperscript{2}]), an increase in serum creatinine by 30% or more than 1 mg/dL [88 μmol/L] over a 24- to 48-hour period indicates the presence of acute renal failure. Methods to measure GFR in this population, such as \textsuperscript{125}I-iothalamate clearance, are cumbersome and costly, especially in the acute care setting. Table 50–6 lists several equations for estimating renal function under these conditions.\textsuperscript{114–116} Although these equations are commonly used to estimate CL\textsubscript{cr} in patients with acute renal failure, a rigorous evaluation of the accuracy and precision of each of these proposed methods is lacking. Also lacking is a method to estimate GFR, an equivalent to the MDRD equation for patients with CKD, for patients with acute renal failure.
The equation proposed by Jelliffe is a revised dynamic model of creatinine kinetics based on theoretical estimates of creatinine production and adjusted for age and changes in serum creatinine; however, its ability to predict changes in drug clearance (and dose adjustments) has not been evaluated. In the acute setting, factors previously discussed that may alter the serum creatinine concentration must be evaluated to avoid misinterpretation. The inappropriate use of the Cockcroft-Gault equation in those with acute renal failure can significantly overestimate the value of \( \text{CL}_{\text{cr}} \) when compared with equations that are designed to account for changes in serum creatinine in patients with unstable renal function. It is thus, ultimately, most important to recognize that renal function in patients with acute renal failure is generally markedly lower than one would estimate using steady-state methods, and dose adjustments should be made if necessary to avoid drug toxicity (see Chapter 51 and Tables 50–7 and 50–8).

**Clinical Controversy**

Serum creatinine values can fluctuate widely in patients with unstable renal function. Although some practitioners advocate the Cockcroft-Gault equation using the highest of the two serum creatinine values, others recommend calculation of \( \text{CL}_{\text{cr}} \) using either the Brater or Jelliffe equation.

**Kidney Function in Children**

Kidney function in the neonate is difficult to assess because of difficulty in urine and blood collection, the frequent presence of a non–steady-state serum creatinine, and the apparent disparity between the development of glomerular and tubular function. Preterm infants demonstrate significantly reduced GFR prior to 34 weeks, which rapidly increases and becomes similar to term infants within the first week of life. Evaluation of GFR in preterm infants on day 3 of life, using an inulin infusion, failed to identify a relationship between patient weight and GFR.

Gestational age, which ranged from 23.4 to 36.9 weeks (mean 30.2 weeks), however, correlated with both GFR and the reciprocal of serum creatinine. The inulin clearance increased from 0.67 to 0.85 mL/min (0.011–0.014 mL/s) in those with gestational age younger than 28 weeks versus those of 32 to 37 weeks of age, whereas \( S_{\text{cr}} \) decreased from 1.05 to 0.73 mg/dL (93–65 μmol/L), respectively. Creatinine was measured using a specific enzymatic method to avoid interference from bilirubin or drugs. Creatinine clearance has also been evaluated in infants younger than 1 week of age, and values of 17.8 mL/min/1.73 m$^2$ (0.171 mL/s/m$^2$) on day 1 increased to 36.4 mL/min/1.73 m$^2$ (0.351 mL/s/m$^2$) by day 6. In light of these rapid changes in GFR, estimation of GFR is not recommended for infants younger than 1 week of age. Kidney function expressed as GFR standardized to body surface area

**TABLE 50–7 Scenario A (Worsening Renal Function)**

J.R. is a 50-year-old man (weight 70 kg, body surface area 1.73 m$^2$) admitted to the intensive care unit following an automobile accident. His renal function was normal prior to admission; however, his serum creatinine has increased from 0.6 mg/dL to 3.0 mg/dL over the past 24 hours.

increases with age and stabilizes at ~1 year. In older children, GFR is best assessed using standard measurement techniques for GFR. Subcutaneous administration of 131I-iothalamate has been effectively used to measure GFR in children ranging in age from 1 to 20 years. 121

Estimation of Clcr as described by Schwartz et al. 122 is dependent on the child’s age and length:

\[
\text{GFR} = \frac{[\text{length} \times (\text{cm}) \times k]}{[\text{S}_{\text{cr}} \text{ in mg/dL}]}
\]

where k is defined by age group: infant (1–52 weeks) = 0.45, child (1–13 years) = 0.55, adolescent male = 0.7, and adolescent female = 0.55.

Subsequent studies verified these relationships in children with normal renal function or mild renal impairment. However, variability increases at clearance values <50 mL/min (<0.84 mL/s). Al-Harbi and Lireman 121 reported a good correlation of the predicted Clcr with measured 4-hour Clcr and 99mTc-DPTA (r = 0.75) in 48 pediatric renal allograft recipients 3 to 19 years of age. However, predictive performance measures of bias and precision were not reported. Fong et al. 124 evaluated the method in critically ill children (mean age 5.6 years, range 0.1–20.8 years) and found that the method significantly overestimated the measured Clcr (bias = 45%). Pierrat et al. 125 compared the MDRD, Schwartz, and Cockcroft-Gault equations in children 3 to 19 years of age. In children younger than 12 years, the Schwartz and MDRD equations were significantly more biased than Cockcroft-Gault, and Cockcroft-Gault provided the best prediction of GFR in children older than 12 years. Because the MDRD equation was developed in the adult population, the results of these investigations suggest that further studies will be needed to clarify the value of any of these predictive methods in children. More recently, an equation for GFR based on BTP was shown to yield similar values of GFR compared with the Schwartz equation in 387 pediatric patients (age 10.7 ± 7.1 years) who underwent a 99mTc-DTPA GFR scan. 126 Dose adjustments and other therapeutic decisions based on kidney function warrant appropriate measures of renal status to avoid incorrect decisions.

### Kidney Function in the Elderly

Cross-sectional studies demonstrate decreased GFR as a function of age when GFR is measured as inulin, iohalamate, or creatinine clearance. 126,127 The Baltimore Longitudinal Study on Aging, 127 an evaluation of 254 normal healthy subjects, revealed that creatinine clearance decreases at the rate of approximately 0.75 mL/min/1.73 m²/y (0.0072 mL/s/m²/y) beginning in the fourth decade of life. These subjects were evaluated prospectively for up to 23 years. Interestingly, approximately one-third of the subjects showed no change in renal function from their baseline value, and a small number showed an increased clearance. These changes may be a result of normal physiologic changes or of subclinical insults to the kidneys initiating the events leading to chronic progressive loss of renal function. Fiser et al. 128 studied renal functional reserve in healthy young (age 23–32 years) and elderly (age 61–82 years) volunteers using an amino acid infusion technique. Inulin clearance was used as the measure of GFR, which increased 16% in young and 17% in elderly subjects following the infusion. Renal functional reserve thus appears to be maintained in healthy elderly individuals.

Interpretation of the serum creatinine concentration alone is difficult in the elderly patient primarily because of the decreased muscle mass and resultant lower production rate of creatinine. Thus, the level of serum creatinine often remains within the normal range despite a reduction in the number of functional nephrons. As renal function declines, the kidneys excrete a larger fraction of creatinine. This perpetuates the “normal” serum creatinine. Recent recommendations, such as the adoption of standardized creatinine assays by clinical laboratories and reporting of serum creatinine values to two decimal places, will likely improve the accuracy of renal function estimation in the elderly population. 75

The Cockcroft-Gault formula 96 can be used to estimate the Clcr of elderly patients. Smythe et al. 129 estimated Clcr in 23 patients older than 60 years using seven different methods and compared the results with a measured 24-hour Clcr determination. Estimations were performed with the actual serum creatinine concentration and also with the serum creatinine rounded up to 1 mg/dL (88 μmol/L) if the actual value was <1 mg/dL (<88 μmol/L). Rounding the serum creatinine to 1 mg/dL (88 μmol/L) resulted in a significantly lower estimate of measured creatinine clearance (~28.8 mL/min [~0.481 mL/s]) compared with the unadjusted serum creatinine (+2.3 mL/min [+0.038 mL/s]). When capping serum creatinine values at 0.68 mg/dL (60 μmol/L), estimation of GFR using the MDRD equation overestimated creatinine clearance by up to 50 mL/min (0.84 mL/min). 130 Until further data are available, fixing or rounding serum creatinine concentration to an arbitrary value in elderly patients is not recommended.

An alternative to the estimation of GFR or a 24-hour clearance determination is a 4-hour clearance performed during water diuresis. This approach correlated with the inulin clearance as well as with an inpatient 24-hour Clcr. 84 However, one must be aware of the potential risk of hyponatremia in the geriatric patient who is unable to tolerate an oral water load, as well as the need for complete bladder emptying to ensure accurate results. O’Connell et al. 131 assessed the accuracy of 2- and 8-hour urine collections compared with 24-hour creatinine clearance determinations in 45 hospitalized patients older than 65 years with indwelling urethral catheters. Single, timed urine collections for Clcr showed minimal bias with the 8-hour collection compared with the 24-hour value, whereas the 2-hour determination was both biased and imprecise.

### Application of Renal Function Estimation Equations for Drug Dosing

As stated previously, creatinine clearance estimated using the Cockcroft-Gault equation remains the most common approach for stratifying patients in pharmacokinetic studies in clinical development and is reported most often in FDA-approved package inserts for new drug entities. 4 A recent survey of pharmacy practitioners indicated that over 95% of individuals use the Cockcroft-Gault...
equation, or a variation using ideal or lean body weight in obese patients, when applied to renal drug dosing. Use of other equations to estimate Clcr may result in drug-dosing errors. For example, Wright et al.\textsuperscript{132} showed that use of the Jelliffe equation in place of the Cockcroft-Gault to calculate the carboplatin dose resulted in obese patients having a 62% lower frequency of dose reductions and toxicity, yet a higher rate of cancer progression, when compared with nonobese patients. Thus, underestimation of GFR resulted in a lower carboplatin dose when compared with the Cockcroft-Gault method. Other modifications to the Cockcroft-Gault equation, including adjustments (or rounding) in serum creatinine to account for “low” serum creatinine values in the elderly, may also result in drug-dosing errors. In patients older than 60 years with serum creatinine < 1 mg/dL (<88 μmol/L), rounding the serum creatinine value up to 1 mg/dL (88 μmol/L) resulted in dose estimates for gentamicin that were significantly lower (~90 ± 67 mg/day) than doses calculated based on the actual serum creatinine value.\textsuperscript{133} In a study by Roberts et al.\textsuperscript{130} of elderly subjects (age 65 ± 13 years), rounding serum creatinine values up to a minimum of 0.68 mg/dL (60 μmol/L) resulted in Clcr estimates that were highly correlated with gentamicin clearance. Although the impact of this rounding approach on errors in drug dosing was not reported, the evidence to date indicates that rounding of serum creatinine values to an arbitrary value should be avoided because of the potential for underdos- ing drugs, especially in the elderly.

The automated reporting of eGFR in the clinical setting has led some practitioners to consider substituting eGFR in place of Clcr for renal dose adjustments. Concerns with this approach include the uncertainty of applying eGFR values to Clcr-based algorithms in package inserts and potential dosing errors and toxicity, especially for drugs with narrow therapeutic indices.\textsuperscript{133–135} Recent studies in over 1,200 patients with renal disease have shown that overestimation of renal function using the MDRD equation results in 30% to 60% higher doses for digoxin, amantadine, and various antimicrobials compared with doses calculated using Clcr estimates.\textsuperscript{136–139} A recent study by Stevens et al.\textsuperscript{140} reported that use of a back-corrected value of eGFR, based on a calculated body surface area (BSA), yields dose calculations that are similar to those calculated using a measured (iohexol) GFR. Use of this back-correction approach has not been validated, and calculating BSA in clinical settings is inconvenient and unlikely to occur. Without back-correction of the eGFR value, the signific- antly higher estimate of renal function may result in dosing errors; this approach is therefore not warranted until studies are conducted to assess the relationship between eGFR estimations and a drug’s pharmacokinetic parameters and/or pharmacodynamic end points. A more detailed discussion of application of renal function estimates and renal dosing approaches is provided in Chapter 56.

**ASSESSMENT OF PROGRESSION**

Chronic kidney disease (see Chapter 52) will eventually lead to end-stage renal disease (see Chapter 53), necessitating dialysis (see Chapter 54) or transplantation for survival (see Chapter 98). The rate of progression can be slowed and in some cases halted through dietary modification, strict blood pressure control, initiation of angiotensin-converting enzyme inhibitor or angiotensin receptor blocker therapy to reduce urinary protein excretion, and improved glucose control in patients with diabetes mellitus (see Chapter 52). The efficacy of these interventions is optimally assessed with the sequential measurement of an accurate and sensitive index of GFR, such as iohexol, iothalamate, or radioisotope clearance.\textsuperscript{141}

Alternatively, newer methods to estimate GFR, such as cystatin C and the MDRD equation, and traditional methods, such as the linear decline in the reciprocal of the serum creatinine concentration as a function of time, are simple clinical tools that can be used to evaluate the rate of progression of renal disease and to predict the time when dialysis will be needed.\textsuperscript{2,20}

Figure 50–3 depicts the change in estimated GFR or Clcr over time in a typical patient with progressive CKD. Clinicians can use the eGFR or Clcr, plotted as a function of time as a prognostic tool, to predict when dialysis may be needed (Clcr <20 mL/min [<0.33 mL/s]) or as a marker for evaluating the success of therapeutic interventions to alter the rate of decline in renal function. Several factors, such as changes in dietary intake of creatinine and decreased muscle mass, which are associated with a reduction in the production of creatinine, may alter the utility of the relationship. Microalbuminuria has been identified as an early marker of renal disease in patients with diabetic nephropathy\textsuperscript{142} and numerous other conditions, such as hypertension and obesity.\textsuperscript{143,144}

Albuminuria is a more sensitive marker than total protein for monitoring CKD progression, as well as a modifiable risk factor for renal disease progression and cardiovascular disease.\textsuperscript{41} Thus, patients with microalbuminuria (30–300 mg/day) on at least two or three occasions or overt albuminuria (>300 mg/day) should begin to receive pharmacotherapy. For children, microalbuminuria is considered present if albumin excretion exceeds 0.36 mg/kg/day, and overt albuminuria has been defined as an excretion rate that exceeds 4 mg/kg/day. The urinary albumin-to-creatinine ratio is also an accurate predictor of 24-hour proteinuria, a marker of renal disease. Guidelines for monitoring indicate that a urine albumin-to-creatinine ratio of >30 mg/g (>3.4 mg/mmol) places the patient at increased risk of developing diabetic nephropathy and is an indication for the initiation of pharmacotherapeutic intervention.\textsuperscript{19} Microalbuminuria has also been suggested as a risk factor for renal dysfunction among patients with essential hypertension.\textsuperscript{40}

**MEASUREMENT OF RENAL PLASMA AND BLOOD FLOW**

Measurement of renal plasma and blood flow is rarely if ever determined in the clinical setting; rather, it is reserved for research settings to evaluate hemodynamic changes related to disease or drug therapy. The kidneys receive ~20% of cardiac output, and
representative values of renal blood flow in men and women of about 1,200 ± 250 and 1,000 ± 180 mL/min/1.73 m² (11.6 ± 2.4 and 9.6 ± 1.7 mL/s/m²), respectively, have been reported. Renal plasma flow (RPF) is estimated to be 60% of blood flow if it is assumed that the average hematocrit is 40% and that it can be measured by the use of model compounds that are eliminated from the plasma compartment on a single pass through the kidneys. Because only 20% of the plasma is filtered at the glomerulus, the compound must undergo active tubular secretion and minimal to no reabsorption to be completely eliminated. To accurately reflect RPF, the extraction through the kidney must be nearly 100%. PAH is an organic anion that has been used extensively for the quantification of renal plasma flow. It is ~17% bound to plasma proteins and is eliminated extensively by active tubular secretion. Because PAH elimination is active, saturation of the transport processes should be anticipated, and concentrations of PAH in plasma should not exceed 10 to 20 mg/L. Dowling et al. used a sequential infusion technique and observed concentration-dependent renal clearance of PAH at concentrations >100 mg/dL (1,000 g/L). Furthermore, PAH is also metabolized, possibly within the kidney, to N-acetyl-PAH, and it is important for the analytical method to differentiate the parent compound and metabolite.

Prescott et al. noted that the renal clearance of PAH decreases at low plasma concentrations, whereas the clearance of the acetyl metabolite increases. Further studies are necessary to evaluate the mechanisms and significance of these findings. The extraction ratio (ER) for PAH is 70% to 90% at plasma concentrations of 10 to 20 mg/L; hence, the term effective renal plasma flow (ERPF) has been used when the clearance of PAH is not corrected for the extraction ratio or if it is assumed to be 1. Normal values are about 650 ± 160 mL/min (10.9 ± 2.7 mL/s) for men and 600 ± 150 mL/min (10.0 ± 2.5 mL/s) for women. Children will reach normalized adult values by 3 years of age, and ERPF will begin to decline as a function of age after 30 years, reaching about one-half of its peak value by 90 years of age. The method for calculation of ERPF is based on the relationship among organ clearance, ER, and flow:

\[
ERPF = \text{renal PAH CL} = \text{RPF} \times \text{ER}
\]

Effective renal blood flow (ERBF) can be estimated from ERPF by assuming the extraction ratio is 1 and correcting for the red blood cell volume of the blood (hematocrit [HCT]):

\[
\text{ERBF} = \text{ERPF}/(1 - \text{HCT})
\]

ERPF can also be measured using the radioisotope I-orthiodihippurate (I-I0H) or Tc-mercaptoacetyltriglycine (Tc-MAG3). One important advantage of this method is its ability to measure ERPF in total or for each kidney independently, as well as its ability to produce renal images. Russell and Dubovsky, using a single-injection technique, compared clearance methods with and without urine collection and showed similar results with each method.

**QUANTITATIVE ASSESSMENT OF TUBULAR FUNCTION**

Although GFR is the best overall indicator of renal function, it may not provide an accurate measure of tubular function, either secretory capacity or cellular function, suitable for use in the research environment. Tubular secretory function can be assessed by measuring PAH transport as the prototype marker of the organic anion secretory system. N-methylhistamine (NMN) and tetracyethylammonium are prototype compounds secreted by the cationic transport system and may be used as markers of cationic secretory capacity. Edwards et al. demonstrated delayed recovery of NMN clearance among patients with psoriasis treated with low-dose cyclosporine, as compared with the recovery of GFR and renal blood flow. Earlier studies with NMN suggested its use to assess the effects of selected renal diseases on drug handling by the kidneys. Dowling et al. explored the usefulness of famotidine as a marker for cationic transport but was unable to demonstrate saturation, perhaps due to the contribution from other parallel secretory pathways, such as P-glycoprotein and multidrug resistance protein 2 (MRP2).

Furthermore, Karyekar et al. demonstrated that itraconazole, a P-glycoprotein inhibitor, significantly reduced the renal tubular secretion of cimetidine in healthy individuals, suggesting that cimetidine may be used as an in vivo probe of renal P-glycoprotein function. It should also be recognized that these transport systems are not necessarily mutually exclusive. Indeed, probenecid, which is secreted by the anionic pathway, inhibits the secretion of cationic compounds. Quantitative measures of tubular transport capacity are currently limited primarily to the research setting.

Other measures of tubular function are less specific and are regarded primarily as indices of damage within the nephron. Low molecular weight proteins located in the proximal tubule, such as β₂-microglobulin, can be used as urinary biomarkers to detect early tubular toxicity for drugs such as carboplatin, ifosfamide, and etoposide. The rise in β₂-microglobulin is related to an early functional defect in the proximal tubular cell. This is followed by a rise in the excretion of enzymes released as a result of structural damage of the cells and, finally, by the formation and excretion of cellular casts. Other low molecular weight proteins used as markers of tubular function are retinol-binding protein (21 kDa), protein HC (also known as α₂-microglobulin, 27 kDa), KIM-1, NGAL, interleukin-18, and fatty-acid binding proteins (FABPs). These proteins are normally freely filtered at the glomerulus and then completely reabsorbed by the proximal tubule. Increases in their excretion are thus suggestive of tubular dysfunction but are not diagnostic, as an increased production rate or GFR less than 30 mL/min may lead to increased excretion. In each case, the maximal reabsorptive capacity may be exceeded, leading to net excretion of the protein.

Numerous urinary enzymes such as N-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, γ-glutamyltransferase, pyruvate kinase, glutathione transferase, lysozyme, and pancreatic ribonuclease have been used as diagnostic markers for renal disease. Jung et al. compared the ability of five enzymes (N-acetylglucosaminidase, alanine aminopeptidase, alkaline phosphatase, γ-glutamyltransferase, and lysozyme) to detect early rejection episodes in kidney transplant patients. Only N-acetylglucosaminidase and alanine aminopeptidase were early predictors of rejection. N-acetylglucosaminidase is an enzyme contained within the lysosome of the tubular cell and is released when the lysosome is damaged, whereas alanine aminopeptidase is an enzyme of the brush border. Both markers were increased approximately 2 days earlier than serum creatinine in patients with transplant rejection.

**QUALITATIVE DIAGNOSTIC PROCEDURES**

**Radiologic Studies**

The etiology of kidney disease can be evaluated using several qualitative diagnostic techniques, including radiography, ultrasonography, magnetic resonance imaging (MRI), and biopsy. The standard radiograph of the kidneys, ureters, and bladder provides a gross estimate of kidney size and identifies the presence of calcifications. Although an easy test to perform, the value of the information is minimal, and more detailed evaluations are
often necessary. The intravenous urogram (formerly known as intravenous pyelogram) involves the administration of a contrast agent to facilitate visualization of the urinary collecting system. It is primarily used in the assessment of structural changes that may be associated with hematuria, pyuria, or flank pain, resulting from recurrent urinary tract infections, obstruction, or stone formation. For patients with low GFRs, retrograde administration of dye into the ureters may be performed to facilitate visualization of the collecting system. Contrast agents are also employed during renal angiography for the assessment of renovascular disease. As a test for the diagnosis of renovascular hypertension, the captopril (angiotensin-converting enzyme inhibitor) test is a useful adjunct. Under conditions of unilateral renal artery stenosis, the affected kidney produces large quantities of angiotensin II, which contracts the efferent arteriole to maintain GFR. The administration of an angiotensin-converting enzyme inhibitor results in reduced uptake of the contrast agent because the efferent arteriole is dilated, thereby decreasing the perfusion pressure of the affected kidney. For patients with bilateral disease, a decrease in uptake is observed in both kidneys. Computed tomography (CT) is a cross-sectional anatomical imaging procedure based on x-ray data. The procedure is frequently performed for contrast to enhance imaging. Spiral, or helical, CT, a more recent technique, provides for three-dimensional reconstruction of tissues. CT is performed as a test for the evaluation of obstructive uropathy, malignancy, and infections of the kidney.

Renal Ultrasonography

Ultrasonography uses sound waves to generate a two-dimensional image. The echogenicity of the kidney is compared with that of an adjacent organ—liver on the right and spleen on the left—with an increased echogenicity indicating an abnormal finding. Ultrasonography can distinguish the renal pyramids, medulla, and cortex, as well as abnormalities in structure, such as those that occur with obstruction. Renal ultrasonography is also used as a guide for site localization during percutaneous kidney biopsy.

Magnetic Resonance Imaging

MRI is based on aligning hydrogen nuclei in the body with the use of a powerful magnet and applying radiofrequency pulses. The signals emitted by the hydrogen nuclei during realignment on repeated pulses allows for generation of the tissue image. Realignment times can also be altered with the use of contrast agents (gadolinium and gadopentetate), leading to increased signal intensity and improved imaging. MRI is useful for the assessment of obstruction, malignancy, and renovascular lesions. The relative advantages and limitations of these procedures are discussed in more detail in recent reviews.

Biopsy

Renal biopsy is used in several conditions to facilitate diagnosis when clinical, laboratory, and imaging findings prove inconclusive. Proteinuria and hematuria are both associated with renal parenchymal disease. When less invasive studies are unsuccessful in differentiating the cause, and the possible causes have different therapeutic approaches, biopsy may be indicated. The functional status of the kidney is not assessed with biopsy, and the severity of disease and progression are best measured using the quantitative tests discussed above. Contraindications to renal biopsy include a solitary kidney, severe hypertension, bleeding disorder, severe anemia, cystic kidney, and hydronephrosis. Complications resulting from biopsy primarily include hematuria, which may last for several days, and perirenal hematoma.

CONCLUSION

The prevalence of kidney disease has increased dramatically over the past 2 decades, indicating a need for early identification, risk classification, and monitoring of renal function in patients with CKD. Comprehensive approaches to evaluating renal function in the clinical setting include the Cockcroft-Gault equation for estimating creatinine clearance and drug dosing, estimation of GFR in patients with CKD, and measurement of urinary protein excretion or albumin-to-creatinine ratio as a marker of the integrity of the glomerular basement membrane. The optimal care of patients identified as having CKD involves treatment modalities aimed at slowing or halting the progression of disease, as described in Chapter 51. Accurate measurement of GFR using exogenous administration of inulin, iothalamate, or radioisotope techniques such as 99mTc-DPTA is typically reserved for research settings to assess drug therapy outcomes and the progression of disease. Use of qualitative assessments of renal function, such as radiography, CT, MRI, sonography, and biopsy, can help to determine the underlying cause of kidney disease.

ABBREVIATIONS

AUC: Area under the plasma concentration versus time curve
CKD: Chronic kidney disease
CKD-EPI: Chronic kidney disease epidemiology collaboration
CL: Clearance

Acute Kidney Injury

WILLIAM DAGER AND JENANA HALILOVIC

KEY CONCEPTS

1. Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Renal Disease (RIFLE) and Acute Kidney Injury Network (AKIN) criteria are two classification systems used to stage the severity of AKI. Both RIFLE and AKIN classes are based on separate criteria for serum creatinine (S_cr) and urine output.

2. Acute kidney injury (AKI) is a common complication in the hospitalized patient and is associated with a high mortality rate.

3. AKI is predominantly categorized based on the anatomical area of injury or malfunction: (a) prerenal—decreased renal blood flow, (b) intrinsic—a structure within the kidney is damaged, and (c) postrenal—an obstruction is present within the urine collection system.

4. Conventional formulas used to calculate the glomerular filtration rate (GFR) and creatinine clearance should not be used to estimate renal function in patients with AKI. Instead, a change in S_cr from baseline and urine output information are more useful in determining the trend and severity of AKI. Currently, several novel biomarkers are being explored to aid in early detection and outcome prediction of AKI.

5. Prevention is key; there are very few therapeutic options for the management of established AKI.

6. Supportive management remains the primary approach to prevent or reduce the complications associated with severe AKI. Supportive therapies include renal replacement therapies (RRTs), nutritional support, avoidance of nephrotoxins, and blood pressure and fluid management.

7. For those patients with prolonged or severe AKI, RRTs are the cornerstone of support and facilitate an aggressive approach to fluid, electrolyte, and waste management.

8. Diuretic resistance is a common phenomenon in the patient with severe AKI and can be addressed with aggressive sodium restriction, combination diuretic therapy, or a continuous infusion of a loop diuretic.

9. Drug-dosing regimens for AKI patients receiving intermittent hemodialysis (IHD) are predominantly extrapolated from data derived from patients with chronic kidney disease (CKD); however, important pharmacokinetic differences exist in patients with severe AKI that should be considered.

10. Drug-dosing guidelines for AKI patients receiving continuous renal replacement therapies (CRRTs) are poorly characterized, and individualized doses may need to be determined by estimating the clearance of medications associated with a high risk of toxicity by the patient and the CRRT procedure.

The development of acute kidney injury (AKI) leading to acute renal failure (ARF) presents a difficult challenge to the clinician because there are many possible causes, and the onset may be asymptomatic. A thorough patient workup is often necessary and includes past medical and surgical history, medication use, physical examination, and multiple laboratory tests. The consequences of AKI can be serious, especially in hospitalized patients, among whom complications and mortality are particularly high. Supportive therapy is the focus of management for those with established AKI, as there is no therapy that directly reverses the injury associated with its numerous causes. Management goals include maintenance of blood pressure, fluid, and electrolyte homeostasis, all of which may be dramatically altered. Additional therapies designed to eliminate or minimize the insult that precipitated AKI include discontinuation of the offending drug (i.e., the nephrotoxin), aggressive hydration, maintenance of renal perfusion, and specific maneuvers to limit or reverse the kidney injury. Because of the poor clinical outcomes and lack of specific therapies, the importance of preventing AKI cannot be overemphasized. Individuals at highest risk, such as those with pre-existing organ failure, including chronic kidney disease (CKD), and the elderly with chronic medical conditions, need to be identified and their exposure to harmful diagnostic or therapeutic procedures or medications minimized.

Renal replacement therapies (RRTs), such as hemodialysis and peritoneal dialysis, have been available for decades but have not resulted in dramatic improvements in the outcomes of patients with AKI. However, newer RRT modalities, including an array of continuous renal replacement therapies (CRRTs), appear to offer some benefits, although available resources may limit their use, and drug dosing is challenging due to a paucity of data. Despite the supportive care that CRRTs offer, the development of AKI is frequently a catastrophic event. In this chapter, the epidemiology and multiple etiologies of AKI, as well as the clinical features associated with the most common types of AKI, are presented. Methods to recognize and identify the extent of functional loss are also discussed. Finally, preventive strategies and management approaches for those with established AKI are reviewed.
DEFINITION OF ACUTE KIDNEY INJURY

Before the first consensus definition of acute kidney injury was published in 2004, there was no agreement on the diagnostic criteria of this complex disorder. Acute renal failure (ARF) was the term commonly used to describe an abrupt decrease in the glomerular filtration rate (GFR) or the more clinically available index of renal function, creatinine clearance (CLcr). The major challenge of using the term ARF was the lack of a universally accepted clinically relevant definition. In fact, more than 30 definitions for ARF have been reported in the medical literature, making comparisons and understanding of epidemiology, treatment, and patient outcome between studies difficult. In 2004, the Acute Dialysis Quality Initiative (ADQI) group published a new consensus-derived definition and classification system for ARF called the Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Kidney Disease (RIFLE) classification. The Risk, Injury, and Failure classes describe the three grades of renal dysfunction based on increasing severity. The patient is assigned a class based on the more severe change in the separate criteria of serum creatinine (S_c) or urine output. Because the S_c criteria are based on its change from baseline, the patient’s renal function prior to the development of renal failure needs to be known. If the baseline measure of S_c, CL_c, or GFR is not available, and the patient has no history of renal dysfunction, one can estimate the baseline S_c value by using the Modification of Diet in Renal Disease (MDRD)\(^2\) equation with an assumed normal GFR of 75 mL/min/1.73 m\(^2\). The last two components of the RIFLE classification are Loss of Kidney Function, defined as the need for RRT for more than 4 weeks, and End-Stage Kidney Disease (ESKD), defined as the need for RRT for more than 3 months.\(^6\)

In 2007, the Acute Kidney Injury Network (AKIN) slightly modified the RIFLE criteria (see Table 51–1 for an overview of both classification systems). The term acute renal failure was replaced by acute kidney injury to emphasize that the disorder exists along a wide continuum, ranging from mild renal dysfunction to the need for RRT. RIFLE-Risk, RIFLE-Injury, and RIFLE-Failure were replaced by AKIN stages 1, 2, and 3, respectively; Loss and End-Stage Kidney Disease were removed from the staging system but retained as outcomes. Also, a time frame of 48 hours was added as a diagnostic criterion to ensure that the process was indeed acute in nature. In an effort to increase the sensitivity of the RIFLE criteria, the change in S_c was lowered from 0.5 mg/dL (44 μmol/L) to 0.3 mg/dL (27 μmol/L) for RIFLE-Risk class. Finally, AKIN criteria place all patients receiving RRT automatically into AKIN stage 3.\(^8\)

So far, the RIFLE classification has gained more recognition than the AKIN staging system, mostly because of the greater number of validation studies published. In addition, the few studies that have compared the RIFLE scoring system with the newly proposed AKIN criteria in critically ill patients have noted no difference in sensitivity or ability to predict outcome.\(^4,5\)

Since the consensus guidelines on AKI were published, multiple studies have validated the ability of the RIFLE criteria to predict certain patient outcomes, particularly hospital mortality.\(^6,7\) When compared with patients without AKI, mortality increases proportionally with the severity of renal dysfunction.\(^8\) This increased risk of death may even persist in patients who recover their renal function after an AKI episode.\(^4,8\) In addition, AKI is associated with increased length of hospital stay, ventilator days, need for RRT, and development of CKD and ESKD.\(^10\)

Even though the RIFLE and AKIN staging systems have led to a standardized and widely accepted classification of AKI, their dependence on S_c and urine output as the main diagnostic criteria is associated with some inherent weaknesses. An increase in S_c is usually evident about 1 or 2 days after development of AKI. This lag time in S_c rise may significantly delay diagnosis of AKI and adversely affect patient outcomes. Urine output reduction emerges earlier in AKI but is a very nonspecific marker because it may not always be present. In fact, patients with AKI can either be anuric (urine output <50 mL/day), oliguric (urine output <500 mL/day), or nonoliguric (urine output >500 mL/day). Urine output will also vary with volume status, diuretic administration, and presence of obstruction.\(^11\)

### EPIDEMIOLOGY

The epidemiology of AKI has been poorly characterized in part due to the lack of a standardized definition, differences in the population under study, and geographical location. AKI is considered to be an uncommon condition in the community-dwelling, generally healthy population, with an annual incidence depending on the definition that ranges from 0.01% to 0.06% (Table 51–2).\(^12\) On the other hand, AKI is significantly more common in hospitalized individuals, with a reported incidence of 7% to 18%. Intensive care unit (ICU) patients have the highest risk of developing AKI, with 36% to 67% of critically ill patients being affected.\(^5,7\)

Increased mortality and morbidity are two well-recognized complications of AKI. Any degree of renal dysfunction is associated with an increased risk of death, particularly if the patient does not recover his or her baseline renal function at the time of hospital discharge.\(^13\) The odds of death increase further with the severity of the RIFLE category.\(^14\) For survivors of AKI, the development of

\(^a\)AKIN criteria require a time constraint of 48 hours for diagnosis. GFR decreases are specified only by RIFLE. In both cases, the criterion that leads to the worst possible diagnosis should be used.

AKIN = Acute Kidney Injury Network, ESKD = end-stage kidney disease, GFR = glomerular filtration rate, RIFLE = Risk, Injury, Failure, Loss of Kidney Function, and End-Stage Renal Disease, RRT = renal replacement therapy, S_c = serum creatinine.
some degree of CKD and need for RRT are other important considerations. Long-term follow-up studies indicate that patients continue to recover renal function up to 6 months after hospital discharge. Even though the majority of patients will recover normal kidney function, ~25% will have CKD, and 12.5% will remain dialysis-dependent.

ETIOLOGY

The etiology of AKI can be divided into broad categories based on the anatomic location of the injury associated with the precipitating factor(s). The management of patients presenting with this disorder is largely predicated on identification of the specific etiology responsible for the patient’s current AKI (Fig. 51–1). Traditionally, the causes of AKI have been categorized as (a) prerenal, which results from decreased renal perfusion in the setting of undamaged parenchymal tissue; (b) intrinsic, the result of structural damage to the kidney, most commonly the tubule from an ischemic or toxic insult; and (c) postrenal, caused by obstruction of urine flow downstream from the kidney (Fig. 51–2).

Community-acquired AKI most commonly occurs secondary to renal hypoperfusion from volume depletion (dehydration, vomiting, and diarrhea), heart failure, or the ingestion of medications such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). Other less common causes include infection (e.g., human immunodeficiency virus [HIV] nephropathy), trauma, rhabdomyolysis, and vascular events. The most common cause of hospital- and intensive care unit (ICU)–acquired AKI is intrinsic, occurring as the result of ischemic or toxic acute tubular necrosis (ATN). The presence of underlying CKD increases the risk of AKI threefold. Other risk factors for developing AKI are advanced age (>65 years), multisystem organ failure, sepsis, preexisting chronic diseases, drugs, infection, surgery, malignancy, and bone marrow or solid organ transplantation. It has been suggested that certain genetic polymorphisms responsible for vascular and inflammatory processes may contribute to the large variability in patient susceptibility to AKI. However, evidence has been relatively inconclusive, and more research with higher quality studies will be necessary to confirm current findings.

PATHOPHYSIOLOGY

PSEUDORENAL KIDNEY INJURY

Pseudorenal AKI is characterized by a rise in either the blood urea nitrogen (BUN) or the $S_{cr}$, which misleadingly may suggest the presence of renal dysfunction, when in fact GFR is not diminished. This could be the result of cross-reactivity with the assay used to measure the BUN or $S_{cr}$ or selective inhibition of the secretion of creatinine into the proximal tubular lumen by certain medications (see Chapter 50). The initiation or discontinuation of such agents should be considered in the assessment for acute changes in renal function and should be looked for as part of the workup in any patient who is suspected of having AKI.

PRERENAL ACUTE KIDNEY INJURY

Prerenal AKI or prerenal azotemia results from hypoperfusion of the renal parenchyma, with or without systemic arterial hypotension. Renal hypoperfusion with systemic arterial hypotension may be caused by a decline in either the intravascular volume or the effective circulating blood volume. Intravascular volume depletion may result from several conditions, including hemorrhage, excessive gastrointestinal (GI) losses (severe vomiting or diarrhea), dehydration, extensive burns, and diuretic therapy. Effective circulating blood volume may be reduced in conditions associated with a decreased cardiac output and systemic vasodilation (e.g., sepsis). Renal hypoperfusion without systemic hypotension is most commonly associated with bilateral renal artery occlusion or unilateral occlusion in a patient with a single functioning kidney.

Patients with a mild reduction in effective circulating blood volume or volume depletion are generally able to maintain a normal GFR by activating several compensatory mechanisms. Those initial physiologic responses by the body stimulate the sympathetic nervous and the renin–angiotensin–aldosterone system and release antiuretic hormone if hypotension is present. These responses work together to directly maintain blood pressure via vasoconstriction and stimulation of thirst, which in conscious patients results in increased fluid intake, as well as sodium and water retention. Additionally, GFR may be maintained by afferent arteriolar dilation (mediated by intrarenal production of vasodilatory prostaglandins, kallikrein, kinins, and nitric oxide) and efferent arteriolar constriction (mainly mediated by angiotensin II). In concert, these homeostatic mechanisms are often able to maintain arterial pressure and renal perfusion, potentially averting the progression to AKI. If, however, the decreased renal perfusion is severe or prolonged, these compensatory mechanisms may be overwhelmed, and prerenal AKI will then be clinically evident.

Patients at risk for prerenal AKI are particularly susceptible to changes in the afferent and effluent arteriolar tone, as they may not be able to compensate as readily. Certain drug classes can interfere with these renal adaptive responses that are normally responsible for maintaining adequate renal perfusion. The resulting reduction in the glomerular hydrostatic pressure precipitates an abrupt decline in GFR and is sometimes referred to as functional AKI. A common cause of this syndrome is a decrease in efferent arteriolar resistance as the result of initiation of an ACE inhibitor or ARB (see Chapter 55). For example, individuals with heart failure are often given an ACE inhibitor or ARB to help improve left ventricular function, but if the dose is titrated too rapidly, they may experience

Renal Disorders

SECTION 5

Acute kidney injury

Clinical history
HPI, PMH, medication history, allergies, rule out pseudorenal causes;

Physical exam
Blood pressure, weight, fluid status, urine output;

Laboratory tests
Chemistry assays, hematologic tests, urine sediment, urinalysis, serologic tests, etc;

Diagnostic tests
Renal imaging, biopsy

Prerenal azotemia

Intrinsic AKI

Postrenal AKI

Volume depletion
Hemorrhage, GI losses, Renal losses (drug-induced or osmotic diuresis, diabetes insipidus), Skin losses (burns), Third-space losses (hypoalbuminemia)

Vascular damage
Renal artery/vein thrombosis, atherothrombolysis, vasculitis, accelerated HTN, HUS or TTP

Glomerular damage
Nephrotic/nephritic glomerulopathies, autoimmune diseases

Acute tubular necrosis
Ischemic
Hypotension, sepsis

Endogenous toxins
Myoglobin, hemoglobin, uric acid, myeloma light chains

Exogenous toxins
Nephrotoxic drugs, contrast dyes

Acute interstitial nephritis

Drugs
NSAIDs, certain antibiotics, etc;

Infection

Bladder outlet obstruction
BPH, malignancy, anticholinergic drugs, displaced bladder catheter;

Ureteral obstruction
Malignancy, retroperitoneal fibrosis, nephrolithiasis;

Renal pelvis/tubular obstruction
Nephrolithiasis, drugs

FIGURE 51–1. Classification of acute kidney injury (AKI) based on etiology. (ACEIs, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; BPH, benign prostatic hyperplasia; GI, gastrointestinal; HTN, hypertension; HUS, hemolytic uremic syndrome; NSAIDs, nonsteroidal antiinflammatory drugs; TTP, thrombotic thrombocytopenic purpura.)

a decline in their GFR. If the increase in the $S_r$ is less than 30% from baseline, the medication can be continued. Another classic example is initiation of ACE inhibitors or ARBs in patients with renovascular disease. It is estimated that ACE inhibitor–induced renal failure occurs in 6% to 23% of patients with bilateral renal artery stenosis and in ~38% of patients with unilateral stenosis who have a single kidney. As a result, administration of ACE inhibitor or ARB therapy in the presence of those conditions is contraindicated. Nonsteroidal antiinflammatory drugs (NSAIDs) may also initiate AKI in susceptible individuals. NSAIDs inhibit renal prostaglandin production and afferent arteriolar vasodilation, which some patients rely on to maintain renal perfusion and GFR. Patients at risk for NSAID-induced AKI include those with CKD, volume depletion, and decreased effective circulating blood volume.

Intrinsic AKI results from direct damage to the kidney and is categorized on the basis of the injured structures within the kidney: the renal vasculature, glomeruli, tubules, and interstitium. Many diverse mechanisms associated with the development of intrinsic AKI are categorized in Figure 51–1.

Renal Vasculature Damage

Occlusion of the larger renal vessels resulting in AKI is not common but can occur if large atheroemboli or thromboemboli occlude the bilateral renal arteries or one vessel of the patient with a single kidney. Atheroemboli most commonly develop during vascular procedures that cause atheroma dislodgement, such as angioplasty and aortic manipulations. Thromboemboli may arise from dislodgement of a mural thrombus in the left ventricle of a patient with severe heart failure or from the atria of a patient with atrial fibrillation. Renal artery thrombosis may occur in a similar fashion to coronary thrombosis, in which a thrombus forms in conjunction with an atherosclerotic plaque.
Although smaller vessels can also be obstructed by atheroemboli or thromboemboli, the damage is limited to the vessels involved, and the development of significant AKI is unlikely. However, these small vessels are susceptible to inflammatory processes that lead to microvascular damage and vessel dysfunction when the renal capillaries are affected. Neutrophils invade the vessel wall, causing damage that can include thrombus formation, tissue infarction, and collagen deposition within the vessel structure. Diffuse renal vasoconstrictive drugs preferentially affect the tubules more than any other large blood components in the intravascular space. Because the glomerulus is a capillary system, similar damage observed in the renal vasculature by the same mechanisms can occur in addition to severe inflammatory processes specific to the glomerulus. The pathophysiology and specific therapeutic approaches to glomerulonephritis are described in detail in Chapter 56.

**Glomerular Damage**

Only 5% of the cases of intrinsic AKI are of glomerular origin. The glomerulus is one of two capillary beds in the kidney. It serves to filter fluid and solute into the tubules while retaining proteins and other large blood components in the intravascular space. Because the glomerulus is a capillary system, similar damage observed in the renal vasculature by the same mechanisms can occur in addition to severe inflammatory processes specific to the glomerulus. The pathophysiology and specific therapeutic approaches to glomerulonephritis are described in detail in Chapter 56.

**Tubular Damage**

Approximately 85% of all cases of intrinsic AKI are caused by ATN, of which 50% are a result of renal ischemia, often arising from an extended prerenal state. The remaining 35% are the result of exposure to direct tubule toxins, which can be endogenous (myoglobin, hemoglobin, or uric acid) or exogenous (contrast agents, aminoglycoside antibiotics, etc.). The tubules located within the medulla of the kidney are particularly at risk from ischemic injury, as this portion of the kidney is metabolically active and thus has high oxygen requirements, yet even in the best of situations, receives relatively low oxygen delivery (as compared with the cortex). Thus, ischemic conditions caused by severe hypotension or exposure to vasoconstrictive drugs preferentially affect the tubules more than any other portion of the kidney.

The clinical evolution of ATN is characterized by three distinct phases: initiation, maintenance, and recovery. The hallmarks of the initiation phase are ischemic injury and GFR reduction, both of which occur as a result of the interplay of several different pathophysiologic processes. Ischemic injury causes tubular epithelial cell necrosis or apoptosis and is followed by an extension phase with continued hypoxia and an inflammatory response involving the nearby interstitium. The loss of epithelial cells between the filtrate and the interstitium leaves the basement membrane denuded and unable to appropriately regulate fluid and electrolyte transfer across the tubular lumen. As a result, the glomerular filtrate starts leaking back into the interstitium and is reabsorbed into the systemic circulation. Additionally, urine flow is obstructed by accumulation of sloughed epithelial cells, cellular debris, and formation of casts. The onset of ATN can occur over hours to days, depending on the factors responsible for the damage to the tubular epithelial cells. Regardless of the etiology; tubular injury, back leakage, and obstruction lead to a loss in the ability to concentrate urine, decreased urine output, and, ultimately, reduction in the GFR. Continued kidney hypoxia or toxin exposure after the original insult kills more cells and propagates the inflammatory response; it also can extend the injury and delay the recovery process. With prolonged ischemia, the tubular epithelial cells in the corticomedullary junction are damaged and die. When the toxin or ischemia is removed, a maintenance phase ensues and may last anywhere from a few weeks to several months. The maintenance phase is eventually followed by a recovery phase, during which new tubule cells are regenerated. The recovery phase is associated with a notable diuresis, which requires prompt attention to maintain fluid balance, or a secondary prerenal injury may occur. However, if the ischemia or injury is extremely severe or prolonged, cortical necrosis may occur, limiting tubule cell regrowth in the affected areas.
**Interstitial Damage**

If the renal interstitium becomes severely inflamed and edematous, it can lead to development of acute interstitial nephritis (AIN). AIN may be caused by drugs (see Chapter 55), infections, and, rarely, autoimmune idiopathic diseases. Whatever the inciting event, acute interstitial injury is characterized by lesions comprised of monocytes, eosinophils, macrophages, B cells, or T cells, clearly identifying an immunologic response as the injurious process affecting the interstitium. If AIN is caused by a drug hypersensitivity reaction, most patients will regain normal renal function within several weeks if the offending drug is promptly discontinued. If symptoms of AIN remain unrecognized, and the exposure to the causative agent continues, persistent renal dysfunction associated with interstitial fibrosis and tubular atrophy may develop.  

**POSTRENAL ACUTE KIDNEY INJURY**

Postrenal AKI accounts for less than 5% of all cases of AKI and may develop as the result of obstruction at any level within the urinary collection system from the renal tubule to the urethra (see Fig. 51–1). However, if the obstructing process is above the bladder, it must involve both kidneys (one kidney in a patient with a single functioning kidney) to cause significant AKI, as one functioning kidney can generally maintain a near normal GFR. Bladder outlet obstruction, the most common cause of obstructive uropathy, is often the result of a prostatic process (hypertrophy, cancer, or infection), producing a physical impingement on the urethra and thereby preventing the passage of urine. It may also be the result of an improperly placed urinary catheter. Neurogenic bladder or anticholinergic medications may prevent bladder emptying and cause AKI. The blockage may occur at the ureter level, secondary to nephrolithiasis, blood clots, sloughed renal papillae, or physical compression by an abdominal process, such as retroperitoneal fibrosis, cancer, or an abscess. Crystal deposition within the tubules from oxalate and some medications severe enough to cause AKI is uncommon, but it is possible in patients with severe volume contraction and in those receiving large doses of a drug with relatively low urine solubility (see Chapter 55). In these cases, patients have insufficient urine volume to prevent crystal precipitation in the urine. Extremely elevated uric acid concentrations from chemotherapy-induced tumor lysis syndrome can cause obstruction and direct tubular injury as well. Wherever the location of the obstruction, urine will accumulate in the renal structures above the obstruction and cause increased pressure upstream. The ureters, renal pelvis, and calyces all expand, and the net result is a decline in GFR. If renal vasoconstriction ensues, a further decrement in GFR will be observed.

**CLINICAL PRESENTATION**

The initiating sign or symptom prompting the clinical suspicion of AKI is highly variable and largely dependent on the underlying etiology. It may be a change in urinary habits (e.g., decreased urine output or urine discoloration), sudden weight gain, or severe abdominal or flank pain. Early recognition and cause identification are critical, as they directly affect the outcome of AKI. One of the first steps in the diagnostic process is to determine if the renal complication is acute, chronic, or the result of an acute change in a patient with known CKD (also called acute-on-chronic renal failure). Patients should also be promptly evaluated for any changes in their fluid and electrolyte status. Patients presenting with AKI in the outpatient environment may have very nonspecific or seemingly unrelated symptoms so that the time of onset of the injury can be difficult to determine. On the other hand, AKI in hospitalized patients is often detected much earlier in its course due to frequent laboratory studies and daily patient assessment.

**PATIENT ASSESSMENT**

The assessment of a patient with AKI starts with a thorough review of his or her medical records, with a particular focus on chronic conditions, medication history, laboratory studies, procedures, and surgeries. An exhaustive review of prescription and nonprescription medicines, herbal products, and recreational drugs may help determine if AKI was potentially precipitated by drug ingestion. Overall, patient presentation varies widely, depending on the underlying cause of AKI. Table 51–3 summarizes the most common physical exam findings associated with different types of AKI.
During the initial patient evaluation, presumptive signs and symptoms of AKI need to be differentiated from a potential new diagnosis of CKD. A past medical history for renal disease–related chronic conditions (e.g., poorly controlled hypertension and diabetes mellitus), previous laboratory data documenting the presence of proteinuria or an elevated \( S_c \), and the finding of bilateral small kidneys on renal ultrasonography suggest the presence of CKD rather than AKI. However, it is important to note that patients with CKD may develop episodes of AKI as well. In that case, an abrupt rise in the patient’s baseline \( S_c \) is one of the most useful indicators of the presence of an acute insult to the kidneys.

An acute change in urinary habits is another common and noticeable symptom associated with AKI. The presence of cola-colored urine is indicative of blood in the urine, a finding commonly associated with acute glomerulonephritis. In hospitalized patients, changes in urine output may be helpful in characterizing the cause of the patient’s AKI. Acute anuria is typically caused by either complete urinary obstruction or a catastrophic event (e.g., shock or acute cortical necrosis). Oliguria, which often develops over several days, suggests prerenal azotemia, whereas nonoliguric renal failure usually results from acute intrinsic renal failure or incomplete urinary obstruction.

Depending on the underlying cause of AKI, patients may present with a variety of symptoms affecting virtually any organ system of the body. Constitutional symptoms such as nausea, vomiting, fatigue, and malaise are common but nonspecific. The onset of flank pain is suggestive of a urinary stone; however, if bilateral, it may suggest swelling of the kidneys secondary to acute glomerulonephritis or acute interstitial nephritis. Complaints of severe headaches may be indicative of drug-induced acute interstitial nephritis or lupus nephritis. A recent increase in the patient’s weight or complaints of tight-fitting rings secondary to salt and water retention indicate prerenal causes and may be helpful in defining the time of onset of kidney injury.

A thorough physical examination is an important step in evaluating individuals with AKI, as clues regarding the etiology can be evident from the patient’s head (eye exam) to toe (evidence of dependent edema) assessment. Observations will either support or refute the cause as prerenal, intrinsic, or postrenal. Evaluation of the volume and hemodynamic status is critical as well, as it will guide patient management. For example, patients with prerenal AKI can present with either volume depletion or fluid overload. Volume depletion may be evidenced by the presence of postural hypotension, decreased jugular venous pressure (JVP), and dry mucous membranes. Fluid overload, on the other hand, is often reflected by elevated JVP, pitting edema, ascites, and pulmonary crackles.

### Laboratory Tests and Interpretation

#### Conventional Markers of Kidney Function

The commonly available laboratory tests used to evaluate the patient with renal insufficiency are described in Chapter 50, and those of particular value in the assessment of renal function in patients with AKI are highlighted in Table 51–4. Over the past 3 decades, \( S_c \) has been the most widely used laboratory test for estimating creatinine clearance (by the Cockcroft-Gault equation), which, in turn, was used as a surrogate marker for GFR. Only in the last 10 years has the multiple versions of the Modification of Diet in Renal Disease (MDRD) equation been used as an alternative method for determining GFR in patients with CKD.

Numerous other equations and markers have been proposed to estimate GFR accurately. However, the Cockcroft-Gault and MDRD 4-variable equations have so far remained the most widely used for estimating renal function in clinical practice.

There are several limitations associated with its use. \( S_c \) varies widely with a patient’s age, gender, muscle mass, diet, and hydration status. For example, patients with reduced creatinine production, such as those with low muscle mass, may have very low \( S_c \) values (<0.6 mg/dL [<53 μmol/L]); thus, the presence of a gradual \( S_c \) rise to normal values (0.8–1.2 mg/dL [71–106 μmol/L]) may actually indicate reduced GFR. When coupled with a decline in urine output, this might suggest the presence of AKI. However, in the presence of improved nutrition and a large muscle mass, an \( S_c \) of 1.2 mg/dL (106 μmol/L) may be a true representation of a person’s current renal status. Instead of using fixed numbers to determine renal function, changes in the value from a patient’s baseline need to be reviewed. \( S_c \) is normally inversely proportional to GFR. However, rapid changes in GFR (as they occur in AKI) disrupt this equilibrium and make \( S_c \) a very insensitive marker. In fact, changes in \( S_c \) will lag behind the GFR’s decline due to slow accumulation, increased tubular secretion, and increased extrarenal clearance.

This can lead to a significant overestimation of the patient’s GFR in the early stages of AKI and consequently a potential delay in the diagnosis of the disorder.

An example of this phenomenon is illustrated by an acute renal artery thrombus that results in abrupt cessation of GFR in one kidney as a consequence of the complete obstruction of blood flow to that kidney (Fig. 51–3). Although 5 minutes following the event GFR is decreased 50% (assuming the other kidney is functioning and unaffected), the \( S_c \) remains unchanged. Assuming a standard daily creatinine production of ~20 mg/kg of lean body weight, one can expect ~1.4 g of creatinine production in a 24-hour period in a 70 kg individual. In pharmacokinetic terms, daily creatinine production is analogous to a continuous infusion, and GFR determines the elimination rate of creatinine. In a patient with normal renal function (GFR of 120 mL/min [2.00 mL/s]), the half-life of creatinine is 3.5 hours, with 95% of steady state achieved in ~14 hours. If GFR declines to 50%, 25%, or 10% of normal, the half-life of creatinine increases, resulting in prolongation of the time to reach 95% of steady state, specifically taking 1, 2, and 4 days, respectively.

*Common laboratory tests are used to classify the cause of acute kidney injury (AKI). Functional AKI, which is not included in this table, would have laboratory values similar to those seen in prerenal azotemia. However, the urine osmolality-to-plasma osmolality ratios may not exceed 1.5, depending on the circulating levels of antidiuretic hormone.*

*The laboratory results listed under Acute Intrinsic Kidney Injury are those seen in acute tubular necrosis, the most common cause of such injury. BUN = blood urea nitrogen, FE Na = fractional excretion of sodium, RBC = red blood cell, \( S_c \) = serum creatinine, WBC = white blood cell."
Because of the challenges associated with the accuracy of $S_c$ in AKI, several GFR calculation methods, such as the Cockcroft-Gault, MDRD, and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations, should not be used in AKI patients with unstable renal function. These equations will typically overestimate GFR when the AKI is worsening and underestimate it when the AKI is resolving. Instead, it may be useful to evaluate changes in $S_c$ values from the patient’s baseline and also consider the $S_c$ sequence values to determine if renal function is potentially improving (values declining) or worsening (values rising). The most recent $S_c$ value reflects the time-averaged kidney function over the preceding time period. Several mathematical approaches to estimate GFR in patients with unstable $S_c$ that incorporate the principles of creatinine accumulation and elimination have been proposed and are discussed in detail in Chapter 50.30,31 These methods have not been extensively validated in the setting of acute alterations in renal function, and their value for adjusting medication dosing is questionable. Additionally, these equations are complex and are not commonly used in the clinical setting.

Two other widely available markers of renal function are BUN and urine output. BUN is widely used to assess hemodialysis adequacy in chronic hemodialysis patients. However, its use in AKI is very limited because urea’s production and renal clearance are heavily influenced by extrarenal factors such as critical illness, volume status, protein intake, and medications. Urine output measured over a specified period of time (e.g., 4–24 hours) allows for short-term assessment of kidney function, but its utility is limited to cases in which it is significantly decreased. The presence of anuria suggests complete kidney failure, whereas oliguria indicates some level of kidney damage. Urine output needs to be interpreted with caution, as it is dependent on several factors, such as hydration status and medications. As mentioned earlier in the chapter, a patient may have AKI and still maintain a normal urine output; this condition is referred to as nonoliguric AKI.

Another approach to measuring renal function when $S_c$ values alone are not reflective of function is to directly measure creatinine clearance over a short period of time, for example, 4 to 12 hours.32 Although potentially precise and fairly simple to do, accuracy is questionable because the urine output is generally low, and if the collection is incomplete, the lost urine can have a dramatic impact on the clearance determination.

Currently, in addition to BUN and $S_c$, selected blood tests, urinary chemistry, and urinary sediment are routinely used to differentiate the cause of AKI and guide patient management. For example, a complete blood cell count with differential can help rule out infectious causes of AKI. Serum electrolyte values are likely to be abnormal because of the acute decline of the kidney’s ability to regulate electrolyte excretion, and particular attention should be paid to serum potassium and phosphorus values, which can be markedly elevated and cause life-threatening complications.

In individuals with normal renal function, the ratio between BUN and $S_c$ is usually less than 15:1 using conventional units (1:16 using SI units). In the presence of prerenal AKI, reabsorption of BUN exceeds that of creatinine; thus, one often sees a ratio greater than 20:1 (1:12.4). Given the limited usefulness of solely using $S_c$ or BUN concentrations to differentiate the etiology of AKI, urinary electrolytes and osmolality should be determined, and both a microscopic and chemical analysis of the urine should be performed (Table 51–5). The finding of a high urinary specific gravity, in the absence of glucosuria or mannitol administration, suggests an intact urinary concentrating mechanism and that the cause of the patient’s AKI is likely prerenal azotemia. The presence of urinary protein is often difficult to interpret, especially in the setting of acute or chronic renal failure. A patient with CKD may have a baseline proteinuria, thus clouding the clinical presentation, unless this is known at the time of AKI assessment. Classically, proteinuria is a hallmark of glomerular damage. However, tubular damage can also result in proteinuria, as the tubules are responsible for reabsorbing small proteins that are normally filtered by all glomeruli. The presence of blood also results in a positive urine protein test, so this confounder must always be assessed when a positive urine protein is obtained. Hematuria suggests acute intrinsic AKI secondary to glomerular injury, infection, or a kidney stone. On microscopic examination, the key findings are cells, casts, and crystals, and the presence of one or more of these suggest specific etiologies of the AKI (Table 51–5). The presence of crystals may suggest nephrolithiasis and a postrenal obstruction. If red blood cells or red blood cell casts are present, one should consider the presence of a physical injury to the glomerulus, renal parenchyma, or vascular beds. The finding of white blood cells or white blood cell casts suggests interstitial inflammation (i.e., interstitial nephritis), which can be secondary to an allergic, granulomatous, or infectious process.

Simultaneous measurement of urine and serum electrolytes is also helpful in the setting of AKI (see Table 51–4). From these values, a
fractional excretion of sodium can be calculated. The equation for the calculation of the fractional excretion of sodium ($\text{FE}_{\text{Na}}$) is

$$\text{FE}_{\text{Na}} = \left(\frac{\text{excreted Na}/\text{filtered Na}}{\text{U}_{\text{Na}}/\text{U}_{\text{cr}}}\right) \times 100$$

$$= \left(\frac{\text{U}_{\text{vol}} \times \text{U}_{\text{Na}}}{\text{GFR} \times \text{S}_{\text{Na}}}\right) \times 100$$

where

$$\text{GFR} = \left(\frac{\text{U}_{\text{vol}} \times \text{U}_{\text{cr}}}{\text{S}_{\text{cr}} \times \text{t}}\right)$$

Thus,

$$\text{FE}_{\text{Na}} = \left(\frac{\text{U}_{\text{Na}} \times \text{S}_{\text{cr}}}{\text{S}_{\text{Na}}}\right) \times 100$$

$$= \left(\frac{\text{U}_{\text{vol}} \times \text{U}_{\text{Na}}}{\text{GFR} \times \text{S}_{\text{Na}}}\right) \times 100$$

where $\text{U}_{\text{vol}}$ is urine volume; $\text{U}_{\text{cr}}$ is urine creatinine concentration; $\text{U}_{\text{Na}}$ is urine sodium; $\text{S}_{\text{cr}}$ is serum creatinine concentration; $\text{S}_{\text{Na}}$ is serum sodium concentration, which usually does not vary much; GFR is the glomerular filtration rate; and $\text{t}$ is the time period over which the urine is collected.

The fractional excretion of sodium is one of the better diagnostic parameters to differentiate the cause of AKI. A low urinary sodium concentration (<20 mEq/L [<20 mmol/L]) and low fractional excretion of sodium (<1%) in a patient with oliguria suggest that there is stimulation of the sodium-retentive mechanisms in the kidney and that tubular function is intact. These findings are most characteristic of prerenal azotemia. Unfortunately, diuretic use in the preceding days limits the usefulness of the fractional excretion of sodium calculation by increasing natriuresis, even in hypovolemic patients. The fractional excretion of urea ($\text{FE}_{\text{Urea}}$), which can be calculated like $\text{FE}_{\text{Na}}$, is sometimes used as an alternative means to assess tubular function.

The inability to concentrate urine results in a high fractional excretion of sodium (>2%), suggesting tubular damage is the primary cause of the intrinsic AKI. Diagnosing the type of AKI using fractional excretion of sodium is not absolute, as there are some intrinsic causes that can be associated with a low fractional excretion of sodium (e.g., contrast nephropathy, myoglobinuria, and interstitial nephritis). Highly concentrated urine (>500 mOsm/kg [>500 mmol/kg]) suggests stimulation of antidiuretic hormone and intact tubular function. These findings are consistent with prerenal azotemia.

### NOVEL BIOMARKERS OF KIDNEY FUNCTION

A number of new serum and urinary biomarkers are currently under investigation for early detection and prediction of prognosis of AKI. They represent a heterogeneous group in their ability to detect, classify, and predict the clinical course of AKI. However, they all allow for a significantly earlier diagnosis of AKI compared with conventional methods, in most cases, 48 hours before a rise in $\text{S}_{\text{cr}}$ is observed. Currently, these tests are not routinely available in most clinical practice sites. Table 51–6 summarizes the characteristics of the six most promising biomarkers that are currently under investigation.

One such marker, serum cystatin C (see Chapter 50), is an endogenous cysteine proteinase that is released into the plasma by all nucleated cells in the body at a relatively constant rate and is then freely filtered by the glomerulus.\(^{26}\) It does not undergo any significant secretion or reabsorption, but is instead completely metabolized by the proximal renal tubules.\(^{31}\) Thus, a reduction in GFR will result in a rise in plasma and urine concentrations of cystatin C. Cystatin C levels may be altered by certain disease states (e.g., thyroid dysfunction and systemic inflammation) and possibly patient demographics (age, weight, gender, etc.).\(^{34-36}\)

Another relatively novel biomarker is neutrophil gelatinase–associated lipocalin (NGAL), a transporter protein found on cell surfaces of neutrophils and various epithelial cells. So far, NGAL has been associated with several physiologic functions, such as iron metabolism, immunity, and kidney development.\(^{37}\) The 2-hour urine NGAL levels correlate well with the severity and duration of AKI and may predict length of stay, need for RRT, and death in patients undergoing cardiopulmonary bypass.\(^{39}\) Although NGAL appears to be a very sensitive, specific, and early biomarker of AKI, its levels may be influenced by the presence of CKD, infection, and inflammation.\(^{39,40}\) Interleukin (IL)-18, a proinflammatory cytokine, is found in elevated urinary concentrations following AKI. In fact, it seems to be specific for ischemic ATN and can distinguish it from CKD, prerenal azotemia, nephrotic syndrome, and urinary tract infections.\(^{41}\) Certain systemic inflammatory and immune-mediated diseases are associated with increased plasma IL-18 levels; however, their impact on urinary IL-18 is still unknown.\(^{42}\) Kidney injury molecule 1 (KIM-1) is a biomarker upregulated in the proximal tubules and released into the urine in response to ischemic and nephrotoxic ATN. One advantage of KIM-1 is that it is not expressed in healthy kidney tissue or detected in plasma. Its production may be induced by exposure to nephrotoxins and the presence of CKD.\(^{42,43}\) Another novel biomarker of AKI is the liver-type fatty acid binding protein (L-FABP), which is found in proximal tubular cells and is involved in fatty acid metabolism in the kidney. Elevated urinary L-FABP levels can be found in CKD as well as in response to oxidative stress and tubulointerstitial damage.\(^{34,45}\) So far, human studies have been limited but have yielded promising results.\(^{46,47}\)

Recently, beta trace protein (BTP), also referred to as lipocalin-type prostaglandin D synthase, has been introduced as a potential marker of GFR. BTP is a glycoprotein expressed in several tissues, most notably in cerebrospinal fluid. It catalyzes conversion of...
Because of the associated risk of bleeding, a renal biopsy is rarely undertaken and should only be performed in those circumstances when a definitive diagnosis is needed to guide therapy, such as the precise etiology of glomerulonephritis (see Chapter 50).

AKI = acute kidney injury, ATN = acute tubular necrosis, BTP = beta trace protein, CKD = chronic kidney disease, GFR = glomerular filtration rate, ICU = intensive care unit, IL-18 = interleukin-18, KIM-1 = kidney injury molecule 1, L-FABP = liver-type fatty acid binding protein, N/A = not available, NGAL = neutrophil gelatinase-associated lipocalin, \( S_\text{cr} \) = serum creatinine.

### DIAGNOSTIC PROCEDURES

When the source of renal injury is unclear after a history, physical examination, and assessment of laboratory values, then imaging techniques such as abdominal radiography, including the kidneys, ureters, and bladder (KUB), computed tomography (CT), and ultrasonography may be helpful. These may reveal small, shrunken kidneys indicative of CKD, and postrenal obstruction can often be identified with a renal ultrasonogram and/or CT scan. Renal ultrasonography is useful in detecting obstruction or hydronephrosis. Nephrolithiasis as small as 5 mm or a narrowing of the ureteral tract can be detected by ultrasonography or more sensitive tests, such as KUB and CT. No contrast dye is required, and it is noninvasive, simple, portable, and rapid to accomplish. In selected conditions under the guidance of a nephrologist, more invasive procedures, such as cystoscopy and biopsy, may be considered to detect the presence of malignancy, prostate hypertrophy, uterine fibroids, nephrolithiasis, or ureterolithiasis.

If insertion of a urinary catheter into the patient’s bladder after the patient has voided or attempted to void does not yield a large volume of urine (>500 mL), then one can usually exclude postrenal obstruction distal to the bladder as the cause of AKI. Cystoscopy with retrograde pyelography may be helpful if the possibility of obstruction exists, and the insertion of a catheter did not result in a significant volume of urine.

In cases in which the cause of ARF is not evident, renal biopsies are useful in determining the cause in the majority of patients. Because of the associated risk of bleeding, a renal biopsy is rarely

### PREVENTION OF AKI

#### DESIRED OUTCOME

Given the dismal outcome of established AKI, it is critical to identify patients at risk and implement prevention strategies when possible. Once AKI occurs, treatment is largely supportive and mainly consists of removing the cause of kidney injury, minimizing subsequent complications, and allowing kidney function to recover. Consequently, the goals of AKI prevention and treatment are to (a) prevent AKI and its complications, (b) avoid or minimize further renal insults that would worsen the existing injury or delay recovery, and (c) provide supportive measures until kidney function returns.

#### GENERAL APPROACH TO PREVENTION

The preventive strategy will depend on the type of renal insult. Clearly, complete avoidance of all potential causes of injury is the most effective preventive method; however, it may not always be possible to implement. Sometimes, the risk of renal injury is predictable, such as decreased perfusion secondary to coronary bypass surgery or secondary to the administration of a radiocontrast dye prior to a diagnostic procedure. In these situations, the potential insult to the kidneys cannot be avoided but may be preventable with aggressive hydration and removal of any additional insults. In the outpatient setting, all healthcare professionals should educate the patient on preventive measures for AKI. Patients should receive counseling regarding their optimal daily fluid intake (~2 L/day) to avoid dehydration, especially if they are
to receive a potentially nephrotoxic medication. In the inpatient setting, hydration, maintenance of a target mean arterial pressure in the critically ill, and avoidance of nephrotoxic medications are commonly implemented strategies for the prevention of AKI.

Generally, prevention strategies are categorized into nonpharmacologic and pharmacologic therapies. It is important to recognize that the strength of supporting evidence varies between the different preventive measures described in the following sections. (See Table S1–7 for a list of proposed therapies and recommendations based on current evidence.)

### NONPHARMACOLOGIC THERAPIES

#### Hydration

Hydration is one of the primary interventions that has consistently shown benefit and is routinely used in the prevention of AKI. Fluids have largely been studied in association with contrast-induced nephropathy (CIN), a common cause of ATN in the inpatient setting (see Chapter 55 for a detailed discussion of CIN). Typically, an increase in the Scr is noted within 24 hours for CIN, peaking after 5 days. CIN is associated with increased mortality especially in individuals with CKD, diabetes, volume depletion, concurrent nephrotoxic drug therapy, or hemodynamic instability. Sodium bicarbonate infusion has recently been evaluated for the prevention of CIN. The hypothesized mechanism for protection is that sodium bicarbonate may reduce the formation of oxygen free radicals by alkalinizing renal tubular fluid. So far, studies have yielded conflicting results, some showing potential benefit, others indicating harm. A recent meta-analysis showed no benefit of extracorporeal blood purification in decreasing the incidence of CIN. In fact, there was a trend toward increased risk of harm when the analysis was limited to studies of hemodialysis. However, the meta-analysis also found that dialysis was initiated at least 1 hour after administration of the contrast media in the majority of the studies. The timing of dialysis is an important consideration, as tubular damage may start to occur after only 15 minutes of exposure to radiocontrast media. Other, more practical issues associated with using prophylactic RRT are cost and the labor-intensive and invasive nature of the procedure itself.

Overall, evidence to date does not demonstrate any consistent significant benefit with the routine use of extracorporeal blood purification to prevent CIN over standard medical therapy.

### PHARMACOLOGIC THERAPIES

#### Loop Diuretics

There is significant controversy surrounding the use of loop diuretics in the prevention of AKI. Early experimental studies proposed that loop diuretics had the following theoretical advantages: decreased risk of tubular obstruction secondary to an increased urine flow and flushing out of debris; increased urine output that may be beneficial in itself, as nonoliguric AKI is associated with better outcomes than oliguric AKI; decreased risk of ischemic injury as the result of inhibition of the sodium/potassium chloride cotransporter and thus a reduction in oxygen demand; and enhanced renal blood flow due to increased availability of renal prostaglandins. However, clinical studies have been less favorable. Even though the majority of studies demonstrate that loop diuretics increase urine output, they lack beneficial effects on patient outcomes, such as mortality, need for RRT, and renal recovery. There is even some evidence of potential harm associated with their use, in particular, ototoxicity and possibly mortality in certain clinical settings. The proposed explanations for such lack of benefit are twofold. Loop diuretics may not be reaching the proximal tubule as their site of action due to tubular obstruction from debris, increased extrarenal clearance secondary to hypoalbuminemia, and increased urinary protein binding due to albuminuria. Also, loop diuretics may actually decrease renal blood flow by reducing effective circulating arterial volume, which, in turn, may stimulate the adrenergic and the renin-angiotensin systems.

### CLINICAL CONTROVERSY

Loop diuretics are widely used for the management of volume overload in critically ill patients, including those with concomitant AKI. Although volume overload is certainly an appropriate indication for loop diuretics, current evidence does not support their use for prevention of AKI or treatment of oliguria.
Dopamine Agonists

Dopamine is a nonselective dopamine receptor agonist that, in high doses, also stimulates the adrenergic receptors. Low doses of intravenous (IV) dopamine (≤2 mcg/kg/min) increase renal blood flow, induce natriuresis and diuresis, and might be expected to increase GFR. Theoretically, this could be considered beneficial, as an increase in renal perfusion and oxygenation might limit ischemic cell injury, inhibition of sodium transport might reduce oxygen demand, and an enhanced GFR might flush nephrotoxins and casts from the tubules. Despite these theoretical suggestions, controlled studies have found that low-dose dopamine did not prevent AKI, need for dialysis, or mortality compared with placebo. Thus, current evidence does not support the use of low-dose dopamine for prevention of AKI.

CLINICAL CONTROVERSY

Despite most studies not showing improved patient outcomes with its use, low-dose dopamine continues to be commonly used. The risks associated with dopamine (extravasation and the potential for significant dosing errors) suggest that its use should be avoided whenever possible.

Fenoldopam mesylate is a selective dopamine A-1 receptor agonist that increases renal blood flow, natriuresis, and diuresis. Although fenoldopam seems ineffective in preventing CIN, it may have some benefit in preventing AKI in critically ill patients or those undergoing surgery.

Antioxidants

Ascorbic Acid

Ascorbic acid has mainly been studied in the prevention of CIN, as its antioxidant properties are thought to alleviate oxidative stress caused by CIN-associated ischemia reperfusion injury. Studies have not consistently demonstrated benefit when ascorbic acid was given to patients with CKD for the prevention of CIN. However, its excellent safety profile and low cost make it an attractive option for high-risk individuals. The recommended dose of ascorbic acid is 3 g orally before the procedure, then 2 g orally twice daily for two doses after the procedure.

N-Acetylcysteine

N-acetylcysteine (NAC) is another antioxidant that has been widely studied in the prevention of CIN in patients with renal insufficiency. However, a therapeutic benefit has not been consistently demonstrated, and large heterogeneity in results across different studies makes it difficult to determine whether NAC is truly effective or not. Similar to ascorbic acid, NAC’s low cost, safety profile, tolerability, and possible benefit make it a reasonable option for patients at risk for CIN. The recommended dosing regimen for prevention of CIN is 600 to 1,200 mg orally every 12 hours for four doses, with the first two doses administered prior to contrast exposure. NAC has also been evaluated for the prevention of AKI in postoperative patients, but studies have failed to demonstrate any benefit. Thus, use of NAC should be reserved for prevention of CIN only and not for other types of AKI.

Glycemic Control

Glycemic control in critically ill patients is of utmost importance, as both hyper- and hypoglycemia are associated with increased mortality. Hyperglycemia is common during critical illness, and one of its key features in that setting is insulin resistance. The causes of insulin resistance are multifactorial but include impaired glucose homeostasis due to loss of the kidney’s metabolic function, as well as decreased hepatic and peripheral glucose uptake secondary to uremia. Hyperglycemia has also been associated with increased risk of renal injury, but the exact mechanisms by which glucose may contribute to renal toxicity are not fully elucidated. Experimental studies indicate increased sensitivity to renal ischemia reperfusion injury, glucose overload in the kidney causing tissue damage, and increased inflammation. Patients may also be at higher risk for hypoglycemia, as the kidneys are the primary metabolic site of insulin.

The target blood glucose concentrations in critically ill patients are controversial. A prospective, randomized controlled study by van den Berghe et al. demonstrated a 41% reduction in the development of AKI and reduced mortality in the intensive insulin therapy group (80–110 mg/dL [4.4–6.1 mmol/L]) compared with the standard control (<200 mg/dL [<11.1 mmol/L]) group of surgical intensive care (ICU) patients. Several other studies, particularly those in nonsurgical ICU patients, failed to reproduce these results. A recent large multicenter randomized study conducted in medical and surgical ICU patients revealed that intensive glucose control was associated with significantly greater 90-day mortality rates and higher risk of hypoglycemia compared with conventional insulin therapy (144–180 mg/dL [8–10 mmol/L]). Although the study did not report the incidence of ICU-acquired AKI, no significant difference in the need for RRT between the two groups was noted. Thus, current evidence suggests that moderate control of blood glucose to levels of 144 to 180 mg/dL (8.0–10.0 mmol/L) may be more appropriate in the critical care setting. Specifically for patients with AKI, it should be recognized that they are at increased risk for hypoglycemia as well as insulin resistance due to altered renal function, so that more frequent glucose monitoring may be required.

OTHER APPROACHES TO PREVENTION

Several other therapies have been investigated for the prevention of AKI. Most of them have shown promising results in experimental studies but the experience in using them in humans is still either inconclusive or limited. One such example is theophylline, which may attenuate adenosine-mediated renal vasoconstriction and GFR reduction in patients with CIN. A systematic review of nine randomized trials indicated a trend toward reduced incidence of CIN with theophylline use. These findings require cautious interpretation as definitions of CIN as well as hydration and theophylline protocols varied markedly. Thus, evidence is currently inconclusive and more research is needed to assess the role of theophylline as a modality for CIN prevention.

Erythropoietin alfa (EPO) is another agent under study for the prevention of AKI. EPO is a primary regulator of red blood cell production and is widely used to treat anemia in patients with CKD and cancer. Experimental models have demonstrated the tissue-protective role of EPO against ischemic renal injury. One small prospective randomized trial has reported that a single dose of EPO (300 units/kg) significantly decreased the risk of postoperative AKI from 29% to 8% after coronary artery bypass surgery. However, a recent double-blind placebo-controlled trial found no difference in the outcome of AKI among 529 enrolled ICU patients. Larger clinical trials would be necessary to demonstrate its safety and efficacy before EPO can be recommended for the prevention of AKI.

Natriuretic peptides, specifically atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP), are also being explored for the prevention of AKI in certain clinical settings. Both ANP and BNP mediate vaso dilatation and natriuresis, as well as increased renal perfusion and GFR. Clinical studies with anaritide (human recombinant ANP) and nesiritide have been relatively inconclusive, but there seems to be growing evidence that lower doses (50 ng/kg/min of anaritide and 0.005 μg/kg/min of nesiritide) and longer infusion...
The proposed explanation for these differences in response is that lower doses of anaritide and nesiritide are associated with lower risks of hypotension, which, if present, may adversely affect renal perfusion and counterbalance any protective effects these drugs may have. Large multicenter, randomized studies are warranted to further clarify the role of natriuretic peptides in the prevention of AKI.

TREATMENT OF AKI

### DESIRED OUTCOMES

Short-term goals include minimizing the degree of insult to the kidney, reducing extrarenal complications, and expediting the patient’s recovery of renal function. The ultimate goal is to have the patient’s renal function restored to his or her pre-AKI baseline.

### GENERAL APPROACH TO TREATMENT

Prerenal sources of AKI should be managed with hemodynamic support and volume replacement. If the cause is immune related, as may be the case with interstitial nephritis or glomerulonephritis, appropriate immunosuppressive therapy must be promptly initiated. Postrenal therapy focuses on removing the cause of the obstruction. It is important to approach the treatment of established AKI with an understanding of the patient’s comorbidities and baseline renal function. Loss of kidney function combined with other clinical conditions, such as cardiac and liver failure, are associated with higher mortality than that associated with the development of AKI alone. At times, the most efficacious remedy for AKI is management of the comorbid precipitating event. Appreciation of the baseline renal function is also important at the outset of AKI management, because the presence of CKD indicates the highest degree of renal function that can be attained after AKI resolution. Finally, the presence of CKD indicates that the kidneys have less reserve; thus, there is a greater likelihood that the individual may not fully recover from the current insult.

1. Supportive care is the mainstay of AKI management regardless of etiology. RRT may be necessary to maintain fluid and electrolyte balance while removing accumulating waste products. The slow process of renal recovery cannot begin until there are no further insults to the kidney. In the case of ATN, the recovery process typically occurs within 10 to 14 days after resolution of the last insult. The recovery period will be prolonged if the kidney is exposed to repeated insults.

### NONPHARMACOLOGIC

Initial modalities to reverse or minimize prerenal AKI include eliminating medications associated with diminished renal blood flow, improving cardiac output, and removing a prerenal obstruction. If dehydration is evident, then appropriate fluid replacement therapy, as described later in this chapter, should be initiated. Moderately volume-depleted patients can be given oral rehydration fluids; however, if IV fluid is required, isotonic normal saline is the replacement fluid of choice, and large volumes may be necessary to provide adequate fluid resuscitation. Typically, IV fluid challenges are initiated with 250 to 500 mL of normal saline over 15 to 30 minutes with an assessment after each challenge of the patient’s volume status. Unless profound dehydration is present, as may be seen in diabetic ketoacidosis and hyperosmolar hyperglycemic states, 1 to 2 L is usually adequate. Patients with diabetic ketoacidosis or a hyperosmolar hyperglycemic state often have a 10% to 15% total-body water deficit, and more aggressive fluid replacement is necessary. The patient should be monitored for pulmonary edema, peripheral edema, adequate blood pressure (diastolic blood pressure >60 mm Hg), normoglycemia, and electrolyte balance. Urine output may not be promptly observed, as the kidney continues to retain sodium and water until rehydration is achieved. Up to 10 L may be required in the septic patient during the first 24 hours, because of the profound increase in vascular capacitance and fluid leakage into the extravascular, interstitial space.

Patients with AKI on top of preexisting CKD should not be expected to produce urine beyond their preexisting baseline. In patients with anuria or oliguria, slower rehydration, such as 250 mL boluses or 100 mL/h infusions of normal saline, should be considered to reduce the risk for pulmonary edema, especially if heart failure or pulmonary insufficiency exists. Other replacement fluids may be considered if the dehydration is accompanied by a severe electrolyte imbalance amenable to large and relatively rapid infusions. For example, dehydration resulting from severe diarrhea is often accompanied by metabolic acidosis caused by bicarbonate losses. A reasonable IV rehydration fluid in this situation is 5% dextrose with 0.45% sodium chloride (NaCl) plus 50 mEq (50 mmol) of sodium bicarbonate per liter, administered as boluses as described above, followed by a brisk continuous infusion (200 mL/h) until rehydration is complete, acidosis corrected, and diarrhea resolved. This fluid will remain mostly in the intravascular space, providing the necessary perfusion pressure to the kidneys, as well as a substantial amount of bicarbonate to correct the acidosis.

If the prerenal AKI is a result of blood loss or is complicated by symptomatic anemia, red blood cell transfusion to a hematocrit no higher than 30% is the treatment of choice. Although albumin is sometimes used as a resuscitative agent, its use should be limited to individuals with severe hypoalbuminemia (e.g., liver disease and nephritic syndrome) who are resistant to crystalloid therapy. These patients have severe hypoalbuminemia-associated third spacing that complicates fluid management, and albumin may be useful in this setting.

The most common interventions that must be made when treating patients with intrinsic or postobstructive AKI involve fluid and electrolyte management. Most patients with these types of AKI, as well as those with a prerenal cause who are excessively fluid resuscitated, ultimately become fluid overloaded. This means drug infusions and nutrition solutions must be maximally concentrated. So-called keep vein open or maintenance IV infusions should be minimized unless the patient is euolemic or is receiving RRT to maintain fluid balance. Supportive care goals for the hospitalized patient with any type of AKI include maintenance of adequate cardiac output and blood pressure to allow adequate tissue perfusion. However, a fine balance must be maintained in anuric and oliguric patients unless the patient is hypovolemic or is able to achieve fluid balance via RRT. If fluid intake is not minimized, edema may rapidly develop, especially in hypoalbuminemic patients. In contrast, a continuous IV infusion of vasopressors, such as dopamine, at doses of ≥2 mcg/kg/min, or norepinephrine when used to maintain adequate tissue perfusion, may also induce kidney hypoxia as the result of a reduction in renal blood flow. Consequently, hemodynamic monitoring may be necessary for critically ill patients (see Chapter 30).

Because there is no current definitive therapy for AKI, supportive management remains the primary approach to prevent or reduce associated complications or death. In the presence of severe AKI, RRTs are commonly prescribed to manage uremia, metabolic acidosis, hyperkalemia, and complications of excess fluid retention, such as pulmonary edema and accumulation of renally cleared medications. Although precise indications for starting RRT are unclear, some general guidelines for therapy have been proposed (Table 51–8).
The ultrafiltration rate is an important determinant in critically unstable patients with AKI. Several CRRT variants have been developed, including continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). They differ in the degree of solute and fluid clearance that can be clinically achieved as a result of the use of diffusion, convection, or a combination of both. Although solute removal is slower, a greater amount can be removed over a 24-hour period compared with IHD, which is associated with improved outcomes in critically ill patients with AKI.

In CVVH, solute and fluid clearance is primarily a result of convection, in which passive diffusion of fluids containing solutes is removed, while volume absent of the solutes is replaced (Fig. 51–4). CVVHD provides extensive solute removal primarily by diffusion, in which solute molecules at a higher concentration (plasma) pass through the dialysis membrane to a lower concentration (dialysate), and some fluid is removed as a function of the ultrafiltration coefficient of the dialyzer. Because the dialysate flows in a countercurrent direction to the plasma flow on the other side of the membrane, the concentration gradient is maximized. CVVHD is associated with a lower incidence of clotting than CVVH because of reduced hemococoncentration, as there is less fluid removal during the process. CVVHDF combines both convection or hemofiltration and hemodialysis, achieving even higher solute and fluid removal rates (Fig. 51–4). The ultrafiltration rate is an important determinant of the effectiveness of all three forms of CRRT; achievement of a removal rate of 35 mL/kg/h is associated with improved survival. However, in direct comparisons of ultrafiltration rates of 25 to 40 mL/kg/h or higher, no difference in mortality has been observed, and there was a tendency toward prolonged need for renal replacement in those who received the higher ultrafiltration rate.

Because of the reduced blood flow rates relative to IHD, thrombosis is a significant concern with CRRT; thus, some form of anticoagulation during RRT is generally necessary for almost all patients. Typical anticoagulation is achieved by the administration of unfractionated heparin, or in some cases, a low molecular weight heparin, direct thrombin inhibitor, or citrate solution. Replacement fluids can be infused either just before or after the dialyzer/hemofilter. Infusing fluids after the hemofilter can result in hemoconcentration within the filter, a factor associated with an increased risk of thrombosis of the dialyzer. Replacing fluids before the filter reduces thrombosis risk, but it also reduces solute clearance.

Disadvantages of CRRT are that not all hospitals have the special equipment necessary to provide these treatments, they require intensive nursing care around the clock, and they are more expensive than IHD because of the need to individualize the IV replacement and dialysate fluids. There is also very little known about drug-dosing requirements for those who are receiving these therapies. CRRT use is most commonly considered for those patients with higher acuity because of their intolerance of IHD-associated hypotension. In one meta-analysis, no difference in clinical outcomes between the two approaches was seen until there was an adjustment for severity of illness. CRRT was then found to be associated with a lower mortality rate. Because patients treated with continuous therapies are almost always more critically ill than those treated by IHD, comparisons of outcome must control for illness severity.

CRRT and hybrid extended-duration intermittent hemodialysis are now being commonly used for critically ill patients with AKI. With CRRT, more solute and water removal can be achieved than with the hemodialysis treatments given three times per week for patients with ESKD. This has influenced how dialysis is prescribed in the intensive care unit for hypercatabolic patients with AKI. Daily IHD is associated with improved survival and faster resolution of AKI compared with dialysis given every other day. Daily delivery of IHD presents challenges to clinicians prescribing drug and nutrition therapy, as most of these dosing guidelines are based on dialysis given three times per week in CKD patients. Thus, application of these guidelines in patients with AKI may yield suboptimal outcomes.

Several renal replacement therapies are commonly used in patients with AKI, including one of the three primary continuous renal replacement therapy (CRRT) variants: (a) continuous venovenous hemofiltration (CVVH), (b) continuous venovenous hemodialysis (CVVHD), (c) continuous venovenous hemodiafiltration (CVVHDF), and the hybrid intermittent hemodialysis therapy (d) slow extended daily dialysis (SLEDD). The blood circuit in each diagram is represented in red, the hemofilter/dialyzer membrane is yellow, and the ultrafiltration/dialysate compartment is brown. Excess body water and accumulated endogenous waste products are removed solely by convection when CVVH is employed. With CVVHD, waste products are predominantly removed as the result of passive diffusion from the blood, where they are in high concentration to the dialysate. The degree of fluid removal that is accomplished by convection is usually minimal. CVVHDF uses convection to a degree similar to that employed during CVVH as well as diffusion, and thus is often associated with the highest clearance of drugs and waste products. Finally, SLEDD employs lower blood and dialysate flow rates than intermittent hemodialysis (IHD), but because of its extended duration, it is a gentler means of achieving adequate waste product and fluid removal.

Hybrid IHD therapies have a variety of names, with the two most common being sustained low-efficiency dialysis (SLEDD) and slow, extended, daily dialysis (see Fig. 51–4). These therapies use lower blood (150–200 mL/min) and dialysate (300–400 mL/min) flow rates with extended treatment periods of 6 to 12 hours. Unlike CRRT, these therapies do not require any new equipment. Anticoagulation is still required, but the amount necessary compared with CRRT is lower. Although the use of hybrid hemodialysis therapies is increasing, our knowledge of the impact of these therapies on drug removal remains limited.

**CLINICAL CONTROVERSY**

Some clinicians believe that CRRTs are preferable to IHD because they provide more consistent fluid and waste product removal. Others suggest that IHD is preferable because the nursing and medical staff is more familiar with its use, and round-the-clock nursing is not needed. New hybrid approaches with slower removal over a prolonged time period may potentially appeal to both groups.
Once the kidney has been damaged by an acute insult (e.g., reduced perfusion or exposure to exogenous or endogenous nephrotoxins), initial therapies should be directed to prevent further insults to the kidney, thereby minimizing extension of the injury. If sepsis is present, antibiotic therapy regimens should be adjusted for decreased renal elimination, the potential for increased elimination if the agent is removed by hemodialysis, and the ability to treat the infection to prevent further damage to the kidney. The time to recovery from AKI is determined from the most recent insult to the kidney, not the first insult. Hospitalized patients with AKI are at high risk for repeated episodes of kidney injury as the result of repeated exposures to nephrotoxic agents and hypotensive episodes, among other problems. These increased risks, coupled with the fact that no drugs have been found to accelerate AKI recovery, dictate the way clinicians approach the AKI patient.

To date, no pharmacologic approach to reverse the decline or accelerate the recovery of renal function has been proven to be clinically useful. Many agents have looked promising in animal trials, only to be found ineffective in human trials. Numerous agents have been investigated and shown no benefit in the treatment of established AKI. In recent years thyroxine, dopamine, and loop diuretics have all been documented to either be of no help or to worsen patient outcomes. For example, a 77% increase in mortality or nonrecovery of renal function was reported in patients with AKI who received a loop diuretic compared with patients who did not receive loop diuretics. These findings may be explained by the fact that sicker, fluid-overloaded patients may be more likely to receive diuretics; nonetheless, no benefit to loop diuretic use could be found in any subanalysis. Consequently, loop diuretic use should be reserved for fluid-overloaded patients who make adequate urine in response to diuretics to merit their use. Prevention of pulmonary edema is an important goal, and it is preferable that it be accomplished with diuretics instead of more invasive RRTs, despite the previously mentioned finding that diuretic use may be associated with diminished outcomes.

The most effective drugs in producing diuresis in the patient with AKI, mannitol and the loop diuretics, have distinct advantages and disadvantages. Mannitol, which works as an osmotic diuretic, can only be given parenterally. A typical starting dose is mannitol (20%) 12.5 to 25 g infused intravenously over 3 to 5 minutes. It has little nonrenal clearance, so when given to anuric or oliguric patients, mannitol will remain in the patient, potentially causing a hyperosmolar state. Additionally, mannitol may cause AKI itself, so its use in AKI must be monitored carefully by measuring urine output and serum electrolytes and osmolality. Adequately designed comparative trials of mannitol to normal saline currently do not exist. Because of these limitations of mannitol, some clinicians recommend that it be reserved for the management of cerebral edema.

Furosemide and bumetanide are the most frequently used loop diuretics in patients with AKI. Ethacrynic acid is typically reserved for patients who are allergic to sulfa compounds. Furosemide is the most commonly used loop diuretic because of its lower cost, availability in oral and parenteral forms, and reasonable safety and efficacy profiles. A disadvantage with furosemide is its variable oral bioavailability in many patients and potential for ototoxicity with high serum concentrations that may be attained with rapid, high-dose bolus infusions. Consequently, initial furosemide doses, which should not exceed 40 to 80 mg, are usually administered intravenously to assess whether the patient will respond. Torsemide and bumetanide have better oral bioavailability than furosemide and are more potent; 4:1 and 40:1 respectively compared to furosemide. Torsemide has a longer duration of activity than the other loop diuretics, which allows for less-frequent administration but which also may make it more difficult to titrate the dose. Loop diuretics all work equally well provided that they are administered in equipotent doses. In a patient who is unresponsive to aggressive IV loop diuretic therapy, switching to another loop diuretic is unlikely to be beneficial.

Diuretic Resistance

The inability to respond to administered diuretics is common in AKI and is associated with a poor patient outcome (Table 51–9). An effective technique to overcome diuretic resistance is to administer loop diuretics via continuous infusions instead of intermittent boluses. Less natriuresis occurs when equal doses of loop diuretics are given as a bolus instead of as a continuous infusion. Furthermore, adverse reactions from loop diuretics (myalgia and hearing loss) occur less frequently in patients receiving continuous infusion compared with those receiving intermittent boluses, ostensibly because higher serum concentrations are avoided. However, these adverse effects still may occur with continuous infusion of loop diuretics and should be monitored. The finding that the continuous infusions of loop diuretics have efficacy that is at least as good as intermittent bolus dosing, with fewer adverse effects, appears to be consistent for all agents, including furosemide, bumetanide, and torsemide. When a continuous loop diuretic infusion is used, an initial loading dose is given (equivalent to furosemide 40–80 mg) prior to the initiation of a continuous infusion at 10 to 20 mg/h of furosemide or its equivalent. Patients with low creatinine clearances may have much lower rates of diuretic secretion into the tubular fluid; consequently, higher doses are generally used in patients with renal insufficiency. Diuretic resistance may occur simply because excessive sodium intake overrides the ability of the diuretics to eliminate sodium. However, other reasons for diuretic resistance often exist in this population. Patients with ATN have a reduced number of functioning nephrons on which the diuretic may exert

ACEIs = angiotensin-converting enzyme inhibitors, N = intravenous, NSAIDs = nonsteroidal antiinflammatory drugs.
its action. Other clinical states, such as glomerulonephritis, are associated with heavy proteinuria. Intraluminal loop diuretics cannot exert their effect in the loop of Henle because they are extensively bound to proteins present in the urine. Still other patients may have greatly reduced bioavailability of oral furosemide because of intestinal edema, often associated with high preload states, which further reduces oral furosemide absorption. Table 51–9 includes possible therapeutic options to counteract each form of diuretic resistance. Combination therapy of loop diuretics plus a diuretic from a different pharmacologic class may be an alternative approach in the setting of AKI. Loop diuretics increase the delivery of NaCl to the distal convoluted tubule and collecting duct. With time, these areas of the nephron compensate for the activity of the loop diuretic and increase sodium and chloride resorption. Diuretics that work at the distal convoluted tubule (chlorothiazide and metolazone) or the collecting duct (amiloride, triamterene, and spironolactone) may have a synergistic effect when administered with loop diuretics by blocking the compensatory increase in sodium and chloride resorption. The combination of loop diuretics and usual doses of thiazide diuretics may be effective in renal disease despite the accumulation of endogenous organic acids in renal disease that blocks the transport of loop diuretics into the lumen. If oral thiazides cannot be given to the patient, chlorothiazide 500 mg, a more expensive option, can be administered parenterally.

Several drug combinations with loop diuretics have been investigated, including the addition of one or more of the following: theophylline, acetazolamide, spironolactone, thiazides, or metolazone. Of these combinations, oral metolazone is used most frequently with furosemide. Metolazone, unlike other thiazides, produces effective diuresis at a GFR <20 mL/min (0.33 mL/s). This combination of metolazone and a loop diuretic has been used successfully in the management of fluid overload in patients with heart failure, cirrhosis, and nephrotic syndrome. Despite a lack of supporting evidence, oral metolazone at a dose of 5 mg is commonly administered 30 minutes prior to an IV loop diuretic to allow time for absorption. Additionally, this combination has been found to be efficacious in pediatric patients in addition to adults. The combination of manitol plus IV loop diuretics is used by some practitioners, but no convincing evidence of the superiority of this combination regimen to conventional dosing of either diuretic alone exists.

## ELECTROLYTE MANAGEMENT

Hypernatremia and fluid retention are frequent complications of AKI; thus, sodium restriction is a necessary intervention. In general, patients should receive no more than 3 g of sodium per day from all sources, including IV fluids, drugs, and enteral intake. Clinicians should be vigilant about sources of sodium. Excessive sodium intake is a common reason diuretic therapy fails. Commonly administered IV antibiotics, as well as other medications, may contain significant amounts of sodium; for example, 1 L of 0.9% NaCl yields 154 mEq (154 mmol; 3.5 g) of sodium. At usual doses, IV metronidazole provides 1.3 g of sodium per day, ampicillin up to 800 mg, piperacillin ~700 mg, and flucloxacil 500 mg. The cumulative effect of a few sodium-containing medications and fluids can be significant.

In continuous and intermittent RRTs, there usually is less concern about hypotension developing because these therapies often incorporate isonatremic (135–140 mEq/L [135–140 mmol/L] of sodium) solutions as the dialysate or ultrafiltrate replacement solutions. Serum sodium concentrations should be monitored daily. Hyperkalemia, hyperphosphatemia, and, to a lesser extent, hypermagnesemia are electrolyte disorders that are frequently seen in patients with AKI. Higher ultrafiltration rates can potentially increase the risk for hyperphosphatemia. The shift in electrolytes is generally not a serious concern in those who are receiving RRT, but electrolytes should be monitored closely in all patients with AKI.

The most common electrolyte disorder encountered in AKI patients is hyperkalemia, as >90% of potassium is renally eliminated. Life-threatening cardiac arrhythmias may occur with serum potassium concentrations >6 mEq/L (6 mmol/L), so potassium restriction is essential. All patients with AKI should have serum potassium monitored at least daily, and twice daily for those who are seriously ill. This frequency is a consequence of the seriousness of the potential arrhythmias, the dynamic nature of potassium serum concentrations in the acutely ill patient, the potential for metabolic acidosis leading to increased extracellular potassium concentrations, and potassium’s ubiquitous presence in foods and some medications. Commonly encountered medications that contain substantial amounts of potassium include oral phosphorus replacement powders (e.g., Neutra-Phos and Neutra-Phos-K) and alkalizers (Polycitra) (see Chapter 59). Many foods are high in potassium, including potatoes, beans, and various fruits. Some medications may promote potassium retention by the kidneys and should also be avoided or closely monitored (see Chapter 55 and 60). Typically, no potassium should be added to parenteral solutions unless hypokalemia is documented. Patients receiving enteral nutrition should be limited to a 3 g potassium diet. Patients receiving RRT should also have their serum potassium concentration measured at least daily. Some centers add no potassium to their CRRT solutions, and hypokalemia can result unless one is prospectively monitoring for its development. Chapter 60 discusses the treatment of hyperkalemia in detail.

Other electrolytes that require monitoring are phosphorous and magnesium. Both are eliminated by the kidneys and are not removed efficiently by dialysis. In the early stages of AKI, hyperphosphatemia may be more common than hypophosphatemia. Patients who have significant tissue destruction (e.g., trauma, rhabdomyolysis, and tumor lysis syndrome) may have significant phosphorus released from the destroyed tissue. Treatment of the hyperphosphatemic state can include CRRT. Calcium-containing antacids should be avoided to prevent precipitation of calcium phosphate in the soft tissues. Typically, the dietary intake of phosphorus and magnesium is restricted, but in patients receiving prolonged renal replacement, deficiency states can occur, particularly in pediatric patients because of their reduced body stores. In contrast to the patient with CKD, calcium balance is usually not an important issue for the patient with AKI because of the limited duration of the illness. One exception to this is seen in patients who are receiving CRRT with citrate as the anticoagulant. Citrate binds to serum calcium, and without an adequate concentration of calcium, blood cannot form a clot. Citrate is thus typically infused before the dialyzer/hemofilter to maintain the dialyzer circuit calcium levels between 0.70 and 1 mEq/L (0.35–0.50 mmol/L). Calcium chloride (10 g of CaCl diluted in 500 mL normal saline) or gluconate (20 g of calcium gluconate to 500 mL normal saline) is then administered prior to returning the blood to the patient to maintain systemic ionized calcium levels between 2.22 and 2.62 mEq/L (1.11–1.31 mmol/L). The citrate that reaches the systemic circulation is subsequently metabolized by the liver. Severe hypocalcemia can result in arrhythmias, even death, so frequent monitoring of unbound serum calcium concentrations is essential.

## NUTRITIONAL INTERVENTIONS

Nutritional management of critically ill patients with AKI can be extremely complex, as it needs to account for metabolic derangements resulting from both renal dysfunction and underlying disease processes, as well as the effects of RRT on nutrient balance. Stress,
inflammation, and injury lead to hypermetabolic and hypercatabolic states and may alter the nutritional requirements. In addition, severe malnutrition found in up to 42% of patients with AKI is a risk factor for increased hospital mortality and length of stay.126 Thus, patient outcomes can be significantly improved if the nutritional status is optimized (see Chapter 153).

Loss of the normal physiologic and metabolic functions of the kidney and the hypercatabolic response to stress and injury will have a significant impact on the metabolism of nutrients. Derangements in glucose, lipid, and protein metabolism result in hyperglycemia and insulin resistance, hypertriglyceridemia, and protein catabolism and negative nitrogen balance (see Chapter 153 for a detailed discussion). The latter, in particular, is problematic to manage, as increased amino acid turnover and skeletal muscle breakdown lead to muscle wasting and malnutrition and do not respond well to increasing exogenous protein supplementation. CRRT is often employed in this patient population to help manage complications such as fluid overload, electrolyte abnormalities, and azotemia. However, CRRT may also remove small water-soluble molecules such as amino acids and certain micronutrients. As a result, patients receiving CRRT will typically have higher protein requirements (1.5–2.5 g/kg/day) and may require additional micronutrient supplementation to account for these losses. The degree of amino acids lost through CRRT depends on the type and modality of CRRT used, duration of dialysis, dialysate flow rate, effluent rate, and type of hemodialfiltration membrane.127

Another nutritional consideration for patients receiving CRRT is the heat loss as a consequence of the cooling of the patient’s blood as it traverses the extracorporeal circuit.128 Even though the blood cooling effect by CRRT is widely recognized in clinical practice, its prevention and effect on energy and nutritional requirements have not been well studied. Limited research on CRRT-induced hypothermia is difficult to compare because of inconsistencies in the definition of hypothermia, as well as differences in types, modalities, and circuit configurations used. It has been proposed that the heat loss can be attenuated by warming the IV ultraltrate replacement solution, but other investigators found no benefit in using fluid warmers to prevent CRRT-induced hypothermia.129 The blood-cooling effect is reported to occur more frequently with venovenous modalities, higher dialysate, and lower blood flow rates. Also, certain patient characteristics, such as female gender, low normal baseline temperature, and low body weight, have been identified as risk factors for hypothermia.128,129 In summary, CRRT should be recognized as a potential source of heat loss. However, no recommendations are currently available for prevention or define the nutritional supplementation that may be necessary as the result of CRRT-induced blood cooling.

DRUG-DOSING CONSIDERATIONS

Optimization of drug therapy for patients with AKI is often quite challenging. The multiple variables influencing responses to the drug regimen include the patient’s residual drug clearance, the accumulation of fluids, which can markedly alter a drug’s volume of distribution, and delivery of CRRT or IHD, which can increase drug clearance and affect the patient’s fluid status to further complicate the clinician’s projection of the optimal dosage regime. For renally eliminated drugs (>30% excreted unchanged in the urine), particularly for agents with a narrow therapeutic range, the urine), particularly for agents with a narrow therapeutic range, serum drug concentration measurements and assessment of pharmacodynamic responses are likely to be necessary. If hepatic function is intact, choosing an agent eliminated primarily by the liver may be preferred. However, any renally eliminated active metabolites may accumulate to a point where they can elicit an undesired pharmacologic effect. Renal failure can also independently impair nonrenal drug elimination that includes metabolism.130 Clinical experiences and pharmacokinetic studies in patients with established AKI are fairly limited. The use of dosing guidelines based on data derived from patients with stable CKD, however, may not reflect the clearance and volume of distribution in critically ill AKI patients (see Chapter 57).103,131

In the volume-depleted patient requiring a renally eliminated medication, dosing regimens based on the initial S cr prior to fluid therapy have the potential to underestimate renal function and drug elimination, resulting in subtherapeutic serum concentrations. Although not accepted as a standard practice, an initial 24-hour dosing regimen with a bolus might be optimal for many patients.

Edema, which is common in AKI, can significantly increase the volume of distribution of many drugs, particularly water-soluble ones with relatively small volumes of distribution. Increased fluid distribution into the tissues (i.e., sepsis and anasarca in heart failure) can also contribute to a larger volume of distribution for many drugs and thereby reduce the proportion of drug in the plasma that is available to be removed by CRRT or IHD. Because AKI frequently occurs in critically ill patients, multisystem organ failure is often an accompanying problem. Reductions in cardiac output or liver function in addition to volume overload can significantly alter the pharmacokinetic profile of many drugs, such as vancomycin, aminoglycosides, and low molecular weight heparins.132,133

In almost all cases where rapid onset of activity is desired, a loading dose may be necessary to promptly achieve desired serum concentrations because the expanded volume of distribution and the prolonged elimination half-life result in an extended time (3.5 times the half-life) until steady-state concentrations are achieved. Maintenance dosing regimens should be reassessed frequently and be based on the patient’s current renal function. A dose that provides the desired serum concentration on one day may be inappropriate only a few days later if the patient’s fluid status, RRT prescription or renal function has changed dramatically.

Drug therapy individualization for the AKI patient who is receiving any form of renal replacement therapy is complicated by the fact that patients with AKI may have a higher residual nonrenal clearance than patients with CKD who have a similar CL cr.134 This has been reported with some drugs, such as ceftriaxone, imipenem, and vancomycin.134–136 Alterations in the activity of some, but not...
all, cytochrome P450 enzymes have been demonstrated in patients with CKD.\textsuperscript{130} The nonrenal clearance of imipenem in patients with AKI (91 mL/min [1.52 mL/s]) is between the values observed in stage 5 CKD patients (50 mL/min [0.84 mL/s]) and those with normal renal function (120 mL/min [2 mL/s]).\textsuperscript{131} This may be the result of less accumulation of uremic waste products that may alter hepatic function. A nonrenal clearance value in a patient with AKI that is higher than anticipated based on data from individuals with CKD would result in lower than expected, possibly subtherapeutic, serum concentrations. For example, to maintain comparable serum concentrations, the imipenem dose requirement in patients with AKI would be 2,000 mg daily as compared with the recommended dosage for patients with ESKD of 1,000 mg daily.\textsuperscript{132} As AKI persists, the nonrenal clearance values appear to approach those observed in patients with CKD.\textsuperscript{133,134,135} Finally, the clearance of aminoglycosides has been reported to be higher and the elimination half-life shorter in those with severe AKI compared with ESKD patients requiring hemodialysis.\textsuperscript{136} Another challenge is that much of the dosing-related data was acquired in patients with CKD, with initial pharmacokinetic assessments done after single-dose administration. The determination of pharmacokinetic parameters using a single-dose model may result in more rapid initial drug removal estimates secondary to distribution from the plasma to the tissue as well. Thus, application of dosing regimens derived from studies in patients with CKD and ESKD may result in underdosing of these agents and thereby contribute to less than optimal clinical outcomes.

### IHD Compared with CRRT

In addition to patient-specific differences, there are marked differences between IHD and the three primary types of CRRT—CVVH, CVVHD, and CVVHDF—with regard to drug removal.\textsuperscript{140–142}

**CRRT** During CVVH, drug removal primarily occurs via convection/ultrafiltration (the passive transport of drug molecules at the concentration at which they exist in plasma water into the ultrafiltrate). Convective removal is most efficient for smaller agents, typically less than 15,000 Da (15 kDa) in size, and those that are primarily unbound in the plasma. The clearance of a drug by either of these methods is thus a function of the membrane permeability for the drug, which is called the sieving coefficient (SC) and the rate of ultrafiltration formation (UFR). Alteration in the pore size of the filter and surface charge relative to the molecule being removed may vary between different dialyzers. If diffusion of the drug is not dependent on the filter pore size, then the SC can be calculated as follows:

$$SC = (2 × C_{UF})/[(C_a) + (C_f)]$$

where $C_a$ and $C_f$ are the concentrations of the drug in the plasma going into and returning from the dialyzer/hemofilter, respectively, and $C_{UF}$ is the concentration in the ultrafiltrate. The SC is often approximated by the fraction unbound ($f_u$) because this information may be more readily available. Thus, the clearance by CVVH can be calculated as

$$CL_{CVVH} = UFR × SC$$

or approximated as

$$CL_{CVVH} = UFR × f_u$$

In CVVHDF, clearance is a combination of both diffusion and convection. The $CL_{CVVHDF}$ can be mathematically approximated, providing the blood flow rate is greater than 100 mL/min and the dialysate flow rate (DFR) is between 8 and 33 mL/min, as

$$CL_{CVVHDF} = (UFR × f_u) + CL_{diffusion}$$

where $CL_{diffusion}$ is the clearance via diffusion from plasma water to the dialysate. In the clinical setting, it is not possible to separate these two components (UFR and DFR) of $CL_{CVVHDF}$. In essence the $CL_{CVVHDF}$ is calculated as the product of the combined ultrafiltrate and dialysate volume ($V_{df}$) and the concentration of the drug in this fluid ($C_d$) divided by the plasma concentration ($C_{p}^{\text{im}}$) at the midpoint of the $V_{df}$ collection period.

**Individualization of therapy for a patient receiving CRRT** is dependent on the patient’s residual renal function and the clearance of the drug by the mode of CRRT the patient is receiving. There are differences in the rate of drug removal, not only between the three primary modes of CRRT, but also within each mode.\textsuperscript{135,140–143} This is a result of differences in the filter membrane composition, variable degrees of drug binding to the membrane, and permeability characteristics of the membrane.\textsuperscript{144–147} The primary factors that influence drug clearance during CRRT are thus the ultrafiltration rate, blood flow rate, and dialysate flow rate. For example, clearance in CVVH is directly proportional to the ultrafiltration rate, whereas clearance during CVVHDF, which depends on both the ultrafiltration rate and the dialysate flow rate, increases as either flow rate increases. An increase in the ultrafiltration flow rate (5–45 mL/min) and dialysate flow rate (8.3–33.3 mL/min), however, can have dramatic effects on the clearance of agents such as ceftazidime during CVVH and CVVHDF, respectively (Fig. 51–5).\textsuperscript{147} Another factor that changes drug dosing is the type of RRT used in the patient. CRRT can rapidly remove excess fluid from edematous patients, thereby changing the volume of distribution ($V_{df}$) of drugs with limited distribution (low $V_{df}$ suggesting a greater proportion in the plasma or extracellular fluid) fairly rapidly. Drug clearances attained by IHD, CRRTs, and hybrid RRTs all differ from each other and must be added to any endogenous drug clearance that the patient generates.\textsuperscript{135} An algorithmic approach for drug dosage adjustment in patients undergoing CRRT has been proposed.\textsuperscript{141} In CRRT, the clearance of a given agent may be ascertained from published reports.\textsuperscript{141,148,149} Table 51–10 summarizes the sieving coefficients of frequently used drugs. These data can be used to design initial dosage regimens for patients receiving CVVH.\textsuperscript{141,143}

For example, IM is a 48-year-old, 60 kg man with an $S_{cr}$ that has increased from 2.3 mg/dL to 7.2 mg/dL (203–636 μmol/L) over 3 days. The residual $CL_{cr}$ value in this patient, calculated using the Jeliffe equation (see Chapter 49), is 4.8 mL/min (0.080 mL/s). The consulting nephrologist recommends that CVVHDF be initiated

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure51-5.png}
\caption{The effect of increasing ultrafiltration rate (UFR in milliliters per minute) and dialysate flow rate (DFR in milliliters per minute) on the clearance of ceftazidime. (Adapted from reference 147.)}
\end{figure}
using a Fresenius F-80 filter at blood, ultrafiltrate, and dialysate flow rates of 150, 15, and 33.3 mL/min, respectively. The patient is to receive cefepime while on CVVHDF. The patient’s residual cefepime clearance (ClRES) can be estimated using the following regression equation relating Clcr and cefepime clearance:

\[ Cl_{RES} (mL/min) = [0.96 \times (Cl_{cr})] + 10.9 \]

\[ Cl_{RES} = [0.96 \times (4.8)] + 10.9 \]

\[ = 15.5 \text{ mL/min (equivalent to 0.26 mL/s)} \]

The total clearance while on CVVHDF would be the sum of the patient’s residual clearance and the cefepime clearance associated with CVVHDF (which can be approximated as described above) as follows:

\[ Cl_{CVVHD} = [(UFR + DFR) \times f_d] \]

\[ Cl_{CVVHD} = [(15 + 33) \times 0.97] \]

\[ = 47 \text{ mL/min} \]

\[ Cl = Cl_{RES} + Cl_{CVVHD} \]

\[ Cl = 15.5 \text{ mL/min} + 47 \text{ mL/min} = 62.5 \text{ mL/min} \]

\[ (\text{equivalent to 1.04 mL/s}) \]

This patient’s clearance value can be used to adjust the cefepime dose as described below. The cefepime clearance in a patient with normal renal function would be calculated as:

\[ Cl_{norm} (mL/min) = [0.96 \times (Cl_{cr})] + 10.9 \]

\[ Cl_{norm} = [0.96 \times 120] + 10.9 \]

\[ = 126.1 \text{ (equivalent to 2.11 mL/s)} \]

The dosage adjustment factor would then be

\[ Q = Cl_{T}/Cl_{norm} \]

\[ Q = 62.5 \div 126 = 0.49 \]

For this patient’s situation, the normal regimen of cefepime would be 2,000 mg (Dn) every 12 hours (\(\tau_f\)). If one wanted to maintain Dn, and extend the dosing interval (\(\tau_f\)), then \(\tau_f\) would be calculated as:

\[ \tau_f = n/Q \]

\[ \tau_f = 12 \text{ hours}/0.49 \]

\[ \tau_f = 24 \text{ hours} \]

This approach suggests the patient should receive cefepime 2,000 mg every 24 hours. If the additional clearance associated with CVVHDF (40.2 mL/min [0.67 mL/s]) was not considered, the calculated dosing interval would have been considerably longer. Several variables can affect the outcome of these calculations, including the multiple variables within the dialysis therapy—for example, UFR, blood flow rate, and DFR—and interpatient variability in nonrenal and renal drug clearance, to name just two.

**Intermittent Hemodialysis** Limitations of IHD-based dosing charts include variability in the patient’s individual pharmacokinetic parameters, differences in the dialysis prescription, such as dialyzer blood flow or duration, and the use of new IHD dialyzers. The approach to hemodialysis may also change on a daily basis, especially in unstable individuals with ARF. This could include, for example, the dialyzer/filter used, the duration, the degree of hemofiltration compared with convection, and the blood flow rate. Individualization of a dosing regimen may require daily assessment of the clinical status of the patient and any planned or recently administered hemodialysis.

Overall, there are numerous potential pharmacokinetic and pharmacodynamic alterations to be aware of in the patient with AKI. Unfortunately, there is a dearth of data to quantify these changes, and even less evidence to prove that if one incorporates these considerations into patient care, the associated outcomes will be improved.

### EVALUATION OF THERAPEUTIC OUTCOMES

Vigilant monitoring of patients with AKI is essential, particularly in those who are critically ill (Table 51–11). Once the laboratory-based tests (e.g., urinalysis and fractional excretion of sodium

</tbody>
</table>
calculations) have been conducted to diagnose the cause of AKI, they usually do not have to be repeated. In established AKI, daily measurements of urine output, fluid intake, and weight should be performed. Vital signs should be monitored at least daily, more often if patient acuity of illness is high. Daily blood tests for electrolytes, BUN, and a complete blood cell count should be considered routine for hospitalized patients.

Therapeutic drug monitoring should be performed for drugs that have a narrow therapeutic window that can be measured by the hospital laboratory. If results from these serum drug concentrations cannot be obtained in a timely fashion (<24 hours), then their value is limited. When considering approaches to measuring serum concentrations, consensus is limited. Measuring a serum drug concentration prior to hemodialysis has the advantage of allowing time for the result to be reported and redosing done shortly after dialysis with minimal delay. This is especially important if the desired pharmacologic effects are lost during or after hemodialysis is complete because the serum concentrations have become subtherapeutic. Knowledge based on previous observations of how a particular agent is removed for a given dialysis approach and any prehemodialysis serum concentration of the agent can assist in estimating the amount removed and predicting any necessary postdialysis dose. Serum concentrations drawn after hemodialysis may reflect plasma concentrations that are transiently depressed until the drug can reequilibrate from the tissues (plasma rebound effect). The advantage with an after-dialysis level is the greater accuracy in determining how much drug was cleared during hemodialysis, but this may delay reestablishing target effects. Greater therapeutic drug monitoring may be necessary in patients with AKI than what is done routinely for other patients because of the potential changes in dynamic status (changing volume status, changing renal function, and RRTs) of patients with AKI.

**PHARMACOECONOMIC CONSIDERATIONS**

AKI is a large financial burden on the healthcare system. Much of this cost is incurred because of extended ICU stays which are inherently expensive. Healthcare costs may also vary by the modality of dialysis a patient is receiving. A post-hoc analysis of a multicenter, multinational study conducted in 2000-01 estimated that the total cost difference between continuous and intermittent RRT in critically ill patients ranges from $3630/day more with continuous RRT to $379/day more with intermittent RRT. In addition, it is estimated that an S<sub>2</sub> increase ≥0.5mg/dL (≥44 μmol/L) is associated with a 6.5-fold increase in odds for mortality, 3.5-day increase in length of stay, and $7,500 (1998 dollars) in excess hospital costs, and average hospital costs in patients requiring RRT are around $50,000. Higher costs have been associated with the severity of AKI using the RIFLE criteria. Most patients who survive AKI regain life-sustaining renal function, but the 5% who do not regain renal function continue to incur the economic and personal costs of dialysis or kidney transplantation. The financial burden is estimated to be over $50,000 per year greater than the non-dialysis-dependent patient whose kidneys recovered from AKI. Nonetheless, patients who required RRT for their AKI generally have a good quality of life after recovery.

Medical intervention costs can be normalized to assess total costs using quality-adjusted life-years (QALYs) gained by the intervention. The use of a QALY approach to treatment of critically ill patients with AKI indicates that treating these patients is very expensive relative to other common medical interventions. For example, in 2001, the treatment of critically ill AKI patient cost per QALY was $168,711, compared with treatment of acute myocardial infarction cost per QALY of $45,000, and the routine treatment of hypertension cost per QALY of $31,321. A typical cost per QALY of <500,000 is considered cost-effective. Another study found that daily hemodialysis was cost effective when compared to alternate-day hemodialysis with about $5000 per QALY gained. Overall, more research needs to be done to improve the AKI survival rate to reduce this cost per QALY. Furthermore, it underscores the need to prevent the occurrence of AKI in the first place.

**CONCLUSION**

The unique characteristics of AKI compared with CKD can lead to notable differences in how renal function is measured and how treatment regimens are developed. Most management approaches currently involve prevention and support of the patient once AKI is established, so as to minimize the potential for additional harm to either the patient or the kidney. Monitoring approaches and pharmacologic regimens should consider frequent changes in the clinical presentations, with most decisions considered short term. Understanding the constantly changing status inherent to AKI and how to adjust management regimens is a key component to optimizing therapy.

KEY CONCEPTS

1. The prevalence of chronic kidney disease (CKD) is estimated at nearly 25 million people in the United States.

2. Because the development of CKD is a complex phenomenon, the Kidney Disease Outcomes Quality Initiative (K/DOQI) has recommended categorizing risk factors associated with CKD as susceptibility, initiation, and progression factors.

3. Reduction of kidney mass, development of glomerular hypertension, and intratubular proteinuria are key mechanisms responsible for the progression of CKD.

4. CKD is classified into five stages based on the presence of kidney structural damage (e.g., proteinuria) and/or kidney function (glomerular filtration rate). Stage 1 is indicative of mild structural changes with “normal” kidney function, while stage 5 is analogous to end-stage renal disease when patients are approaching the need for dialysis or kidney transplantation.

5. Serum creatinine concentration is not a reliable marker of kidney function among the elderly, the malnourished, and children. Therefore, it is important to estimate the glomerular filtration rate rather than just measuring the serum creatinine, especially in these three populations.

6. Stage 5 CKD manifests as asterixis, pruritus, dysgeusia, nausea, vomiting, anorexia, weight loss, and susceptibility to bleeding. These signs and symptoms of uremia drive the decision to implement kidney replacement therapy.

7. The progression of CKD can be slowed by optimizing blood pressure control and among diabetics blood glucose control.

8. Diabetic patients with or without hypertension who demonstrate persistent microalbuminuria despite intensive insulin therapy should have their angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB) dose titrated to achieve maximal suppression of urinary albumin excretion to halt or slow CKD progression.

9. ACEIs and ARBs are key pharmacologic treatments of chronic kidney disease because of their hemodynamic and blood pressure reduction effects, which help to limit kidney disease progression.

10. Dietary protein restriction, lipid-lowering interventions, cessation of smoking, and symptom control of anemia have been suggested to slow the rate of progression of CKD; however, the utility of these interventions remains unclear.

Under normal conditions each of the 2 million nephrons of the kidneys work in an organized fashion to filter, reabsorb, and excrete various solutes and water. The kidney is the primary regulator of sodium and water balance, as well as of acid-base homeostasis. The kidney also produces hormones necessary for red blood cell synthesis and calcium homeostasis. Dysregulation of kidney function is classified as acute kidney disease and chronic kidney disease. Acute kidney failure refers to the rapid loss of kidney function over days to weeks. Chronic kidney disease (CKD), also called chronic renal insufficiency or progressive kidney disease by some, is defined as a progressive loss of function occurring over several months to years and is characterized by the gradual replacement of normal kidney architecture with parenchymal fibrosis.

The working group of the National Kidney Foundation’s (NKF) Kidney Disease Outcomes and Quality Initiative (K/DOQI) has developed a CKD classification system based on the presence of structural kidney damage and/or functional changes in glomerular filtration rate (GFR) present for a period of 3 months or more. CKD is categorized by the level of kidney function (as defined by GFR) into stages 1 through 5, with each increasing number indicating a more advanced stage of the disease (Table 52-1). The use of GFR versus serum creatinine concentration (henceforth, serum creatinine) to define the stages of CKD was chosen because the serum creatinine alone is an inaccurate index of kidney function and there is marked variability in GFR among subjects with similar serum creatinine values (see Chap. 50). Although the stages are defined functionally by the GFR, the classification system also accounts for

structural evidence of kidney damage. Normal kidney function in adults is approximately 120 mL/minute/1.73 m² (1.16 mL/s/m²) based on measured GFR. Even though a GFR of >90 mL/minute/1.73 m² (>0.87 mL/s/m²) is considered normal kidney function, a patient can be diagnosed with stage 1 CKD if the patient has proteinuria, hematuria, or evidence via a kidney biopsy of structural damage. Stage 5 CKD was previously referred to as end-stage renal disease (ESRD) or end-stage kidney disease. As a note to the clinician, a Medicare ICD-9 code exists for stage 6 CKD and is primarily for the purposes of billing for services. This designation represents patients with ESRD [eGFR<15mL/min/1.73m² (0.14 mL/s/m²)] receiving renal replacement therapy. In this chapter, stage 5 CKD will refer to patients with eGFR<15mL/min/1.73m² (0.14 mL/s/m²) or patients receiving replacement therapy in order to maintain consistency with the CKD literature.

### EPIDEMIOLOGY OF CKD

1. The epidemiology of stage 5 CKD, or ESRD, has been well documented through the efforts of the USRDS, a national data system that collects, analyzes, and distributes information about U.S. patients on hemodialysis and peritoneal dialysis, as well as kidney transplant recipients.² Beginning in 2008, the USRDS Report has also included data regarding the earlier stages of CKD, drawing from both National Health and Nutrition Examination Survey (NHANES) data and claims data. In NHANES III and subsequent populations, the prevalence of CKD at any stage using present definitions is estimated between 13% and 16%, representing over 25 million individuals.³,⁴ Stage 3 CKD [eGFR <60mL/min/1.73 m²] has risen from 5.7% in NHANES III (1988–1994) to 8.1% in the more recent NHANES population (2003–2006).⁵ Claims data for 2006 suggest that CKD prevalence among those 65 years or older is 6.4% using traditional claims codes and 4.2% using the more recent coding system.⁶ Although less than that in NHANES, the data represent a significant increase in CKD prevalence likely due in part to increases in awareness and reporting. The CKD prevalence is similar to that of other chronic conditions such as hypertension, diabetes mellitus, and cardiovascular disease.

In the United States alone, there are several major epidemiologic studies in progress to better describe the natural history of CKD, its progression, and concurrent morbidities. One study targets individuals with polycystic kidney disease,⁷ while another study targets African Americans with hypertensive nephrosclerosis.⁸ The Chronic Renal Insufficiency Cohort (CRIC) study, funded by the National Institutes of Health⁹ and the Fresenius and Amgen, Inc. cosponsored study (Stride Registry)⁰ are investigating progressive CKD and its relationship with comorbid cardiovascular disease. The NKF has recognized the importance of early detection and initiated the Kidney Early Evaluation Program (KEEP)¹¹ to provide free screening and education for people at high risk of developing kidney disease. Baseline characteristics have largely confirmed the previously reported demographic and clinical factors associated with CKD.¹²,¹³ Perhaps some of the most alarming data from KEEP was the low awareness of the disease. Less than 10% of patients were aware of this diagnosis, and even among those with later stages of CKD (stages 3 to 5) only 11% of patients were aware of the diagnosis.¹⁴

USRDS estimates of new cases of stage 5 CKD necessitating renal replacement therapy increased by 5% to 10% per year during the two decades spanning 1980 to 2000.² However, since 2002, the rate of increase had declined to less than 1% to 2% per year.² A potential factor attributed to this decline has been the implementation of angiotensin-converting enzyme inhibitor (ACEI) and angiotensin receptor blocker (ARB) therapy as a standard of care for those with early stage CKD.¹² At present, the four most common causes of incident stage 5 CKD in the United States are diabetes mellitus (158 cases per million), hypertension (101 cases per million), glomerulonephritis (25 cases per million), and polycystic kidney disease (9 cases per million).²

2. It is often assumed that all patients with stage 1 or 2 CKD progress continuously toward stage 5. Thus, information on risk factors obtained from USRDS data is assumed to be generalizable to all stages of CKD. Early data from the KEEP and CRIC studies offer some support for this assumption.¹⁴,¹¹ However, further complicating these issues is the fact that the development and progression of the early stages of CKD is a complex phenomenon.¹⁵ The risk factors associated with CKD are numerous and varied and many of these are not those one would traditionally consider as having a direct influence on the causal pathway. The working group of K/DOQI has recommended categorizing CKD risk factors as susceptibility factors, initiation factors, or progression factors to help clinicians stratify the overall risks of individual patients (Table 52–2).¹⁶

In this chapter the initiation and progression factors associated with the development of CKD are reviewed. Because diabetes mellitus and hypertension are the two most prevalent etiologies for CKD, the course and treatments that have been proven to slow the progressive kidney function decline are critically evaluated. This chapter focuses on the early CKD stages, that is, stages 1, 2, and 3, which are the critical battleground if one hopes to minimize the number of patients who ultimately require renal replacement therapy. CKD is a continuous and progressive disease state that often results in the appearance of several concomitant complications that commence at various stages in the progression of the disease. The pathophysiology, consequences, and complications of CKD that tend to become evident in those with stage 4 or 5 CKD are discussed in Chap. 53 along with treatment options and monitoring parameters.

### ETIOLOGY

#### SUSCEPTIBILITY FACTORS

CKD susceptibility factors include advanced age,¹³ low income or education,¹⁶,¹⁷ and racial/ethnic minority status,¹⁸ as well as reduced kidney mass,¹⁹ low birth weight,¹⁹,²⁰ and family history of CKD.²¹ These factors have not been proven to directly cause kidney damage. Novel proposed susceptibility factors are systemic inflammation,²²,²³ and dyslipidemia.²⁴,²⁵ Although, most of these susceptibility factors

---

768

SECTION 5

Renal Disorders
are not amenable to pharmacologic or lifestyle interventions, they are useful for identifying populations that are at high risk of CKD.

**INITIATION FACTORS**

Initiation factors are conditions that directly result in kidney damage and are modifiable by pharmacologic therapy. Diabetes mellitus, hypertension, autoimmune diseases, polycystic kidney disease, systemic infections, urinary tract infections, urinary stones, lower urinary tract obstruction, and nephrotoxicity are all considered initiation factors. Because diabetes mellitus, hypertension, and glomerular diseases are, respectively, the three most common causes of CKD in the United States, the following discussion focuses on these conditions.

**Diabetes Mellitus**

Approximately 20% to 40% of those with diabetes mellitus will develop diabetic CKD.26 Given the greater prevalence of type 2 diabetes mellitus, the majority of patients who develop diabetes-associated CKD are those with type 2 disease. Although not all individuals with diabetic nephropathy progress to stage 5 CKD, the lifetime risk is considerable. A prospective study of over 300,000 individuals screened from the Multiple Risk Factor Intervention Trial estimated that approximately 3% of individuals with diabetes mellitus will develop stage 5 CKD.27 Diabetics have a 12-fold greater relative risk of developing stage 5 CKD than those without diabetes. Diabetics also have an increased risk of developing CKD as the result of a “nondiabetic” cause, suggesting an underlying genetic susceptibility to kidney diseases.28

**Hypertension**

Hypertension also increases the risk of CKD, although the exact role as a cause or consequence is often debated as the kidney has a role in the development and modulation of high blood pressure. Hypertension generally develops concomitantly with progressive kidney disease. In the NHANES III survey, a serum creatinine of 1.6 mg/dL (141 μmol/L) or higher for men and 1.4 mg/dL (124 μmol/L) or higher for women was more common in persons with hypertension (9.1%) than in persons without hypertension (1.1%).29 Recent data suggest that among patients with an estimated GFR of 20 to 70 mL/min/1.73 m², over 85% have concomitant hypertension.30

Prospective studies have shown that elevated blood pressure increases the risk for the development of CKD among subjects without initial kidney disease. In a study of 316,675 adult managed-care patients with normal baseline kidney function, the likelihood of incident ESRD (stage 5 CKD) was increased in those with elevated baseline blood pressure. The likelihood of CKD development was twofold higher for those with relatively minor elevations in blood pressure, 120 to 129 mm Hg systolic over 80 to 84 mm Hg diastolic as compared with those with blood pressure lower than 120/80 mm Hg. For those with blood pressure greater than 210/120 mm Hg, the likelihood of CKD was fourfold higher.31

Data from the Multiple Risk Factor Intervention Trial, a primary prevention trial in coronary heart disease, demonstrated that the overall lifetime risk of developing stage 5 CKD for individuals with hypertension was 5.6%.32 The risk varied dramatically by level of blood pressure, from 0.33% in those with stage 1 hypertension (systolic blood pressure 140 to 150 mm Hg and/or diastolic blood pressure 90 to 100 mm Hg) to 4.5% for systolic blood pressure levels greater than 180 mm Hg or diastolic blood pressure levels greater than 110 mm Hg over a follow-up period of approximately 16 years.32

**Glomerulonephritis**

Glomerular diseases are also considered initiation factors of CKD. The epidemiology and pathophysiology of glomerular diseases are variable, and thus all diseases should not be lumped into one disease category. Some conditions, such as Goodpasture’s disease or Wegener’s granulomatous, may progress rapidly to stage 5 CKD and thus may best be categorized as causes of acute renal failure. Other conditions such as immunoglobulin A (IgA) nephropathy, membranous nephropathy, focal segmental glomerulosclerosis, and lupus nephritis are more indolent and are considered causes of CKD (see Chap. 56). The chronic glomerular diseases progress at variable rates, with loss of GFR ranging from 0.9 to 9.8 mL/min per year.33-35

**PROGRESSION FACTORS**

Progression risk factors are those associated with further declines in renal function. Persistence of the underlying initiation factors (e.g., hypertension, diabetes mellitus, glomerulonephritis, and polycystic kidney disease) themselves may serve as the most important predictors of progressive CKD. Other factors associated with progression include those that may be consequent to the underlying renal disease (hypertension, proteinuria, hyperlipidemia) or independent of the underlying renal disease (smoking, obesity).

**Hypertension**

The early treatment of hypertension and the achievement of aggressive target values has been demonstrated to slow the rate of progression of CKD.36 Bakris et al. demonstrated a direct correlation between the level of achieved blood pressure and preservation of kidney function in diabetic patients.37 Their analysis included 10 studies measuring a change in GFR for diabetic patients treated with various antihypertensive agents. An inverse linear relationship was observed between average attained blood pressure at study completion and average GFR; lower final mean arterial blood pressure resulted in a lower average decline in GFR. Specifically, a systolic blood pressure of 180 mm Hg was associated with a 14 mL/min per year decline in GFR as compared with only a 2 mL/min per year decline in GFR among those with a systolic blood pressure of 135 mm Hg.38

An extended follow-up analysis of the MDRD original cohort showed that patients assigned to lower blood pressure target (mean arterial pressure <92 mm Hg) were 32% less likely to develop stage 5 CKD than those in the usual target blood pressure (mean arterial pressure <107 mm Hg).39 Therefore, low blood pressure slowed the progression of nondiabetic kidney disease even for patients with an existing moderately to severely decreased GFR.

**Diabetes Mellitus**

Hyperglycemia is an initiation and progression risk factor for CKD. Diabetic nephropathy represents the most common cause for ESRD.2 In the NHANES population 1999 to 2006, the diagnosis of diabetes is associated with a 2.51 (2.07–3.02, P<0.001) odds ratio for CKD, representing the greatest risk factor after older age.4 The likelihood of developing overt nephropathy varies between type 1 and type 2 diabetes mellitus. Without treatment, nearly 80% of patients with type 1 diabetes and microalbuminuria will develop overt nephropathy and nearly 50% of those with type 1 diabetes, nephropathy and hypertension will develop ESRD within 10 years.40,41 In contrast, only 20% to 40% of those with type 2 diabetes for over 15 years will demonstrate progressive disease.42 A recent evaluation of participants in the Diabetes Control and Complications Trial (DCCT) and the Epidemiology of Diabetes Interventions and Complications (EDIC) study suggests the historical estimates of diabetic nephropathy may be inflated, since 17% to 25% of their type 1 diabetic participants developed diabetic nephropathy after 30 years.43 It is not clear whether the lower incidence represents an improvement in overall care or simply is a by-product of enrollment in these studies. Progression of diabetic nephropathy likely has multiple determinants including...
both hypertensive and glycemic control and therefore occurs at a variable rate. As will be discussed, control of both blood pressure and hyperglycemia may attenuate progression of diabetic CKD.

Proteinuria

The importance of proteinuria in the progression of both diabetic and nondiabetic kidney disease has been well documented. In diabetic kidney disease (types 1 and 2), an albumin excretion rate higher than 30 mg per 24 hours (microalbuminuria) strongly predicted the development of overt nephropathy (proteinuria) and subsequent loss of kidney function. In nondiabetic kidney disease, the Modification of Diet in Renal Disease (MDRD) Study—a randomized clinical trial examining oral protein restriction and blood pressure control on progression of preexisting CKD, demonstrated that a patient’s baseline level of proteinuria strongly predicted future loss of GFR. Furthermore, individuals with the highest levels of baseline proteinuria benefited most from pharmacologic reduction of blood pressure. Another study of more than 1,800 individuals with varying stages of CKD demonstrated a strong, graded risk of CKD based on the level of proteinuria; a fivefold increased risk of progression was observed for each 1.0 g/day increase in proteinuria.43

The joint role of blood pressure and proteinuria in the progression of CKD was investigated by Jafar et al. using data from 11 randomized, controlled trials that compared the efficacy of antihypertensive regimens for patients with predominantly nondiabetic kidney disease.45 Patients with higher systolic blood pressures and urine protein excretion greater than 1.0 g/day had greater risk for progression of CKD. (P<0.006).

Smoking

Although the adverse effects of smoking on cardiovascular disease are well documented, only recently have the consequences of smoking on the progression of CKD been recognized. Smoking is associated with an acute reduction in GFR and increased heart rate and blood pressure, likely secondary to nicotine exposure.46 Nicotine has also been associated with an increase in urinary albumin excretion.46

Significant data exist to suggest that smoking may promote initiation and progression of CKD in subjects with type 1 and type 2 diabetes.46-47 The "cigarette pack years" was an independent predictive factor for CKD progression among diabetic subjects.46 In addition, smoking has also been associated with the diagnosis of CKD in those with hypertension, especially among black subjects.46 Some studies have demonstrated an association between smoking and albuminuria46 and the development of stage 5 CKD. Baseline data from the aforementioned CRIC study also demonstrate a modest association between smoking and CKD.10 Smoking has also been identified as a risk factor for progression in patients with IgA nephropathy, polycystic kidney disease, and systemic lupus erythematosus.46,52

Hyperlipidemia

Dyslipidemia may be associated with kidney disease. CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. The prevalence of hyperlipidemia appears to increase as kidney function declines, and hyperlipidemia is a characteristic of the nephrotic syndrome.53 Elevated plasma total and low-density lipoprotein cholesterol occurs in 85% to 90% of patients with decreased kidney function and proteinuria greater than 3 g/day. Approximately 50% of these patients have low levels [<35 mg/dL (<0.91 mmol/L)] of high-density lipoprotein cholesterol, and 60% have triglyceride concentrations greater than 200 mg/dL (2.26 mmol/L).53 Three epidemiologic studies24,25,54 demonstrated that dyslipidemia predicts incident CKD among individuals considered at low risk for CKD.55

Obesity

Several studies have evaluated the association between obesity and development of CKD.46,57 Iseki et al. examined the relationship between body mass index (BMI) and the development of ESRD from a large population of Japanese subjects participating in a community-based screening.57 BMI was associated with an increased risk of the development of ESRD in men but not in women. Population data from Kaiser Permanente revealed an increased risk of ESRD in overweight and obese subjects.56 The risk of ESRD was directly related to the magnitude of obesity and remained even after adjustment for diabetes and hypertension.56

Another study showed that a BMI ≥25 kg/m² at age 20 years is associated with a threefold increase in risk of CKD compared with a BMI lower than 25 kg/m². Obesity (BMI ≥30 kg/m²) among men and morbid obesity (BMI ≥35 kg/m²) among women were associated with three- to fourfold increases in risk.58

More recent studies have provided some conflicting data. The Framingham Offspring Study demonstrated an increased risk for CKD among the obese (BMI ≥30 kg/m²) but not among the overweight (BMI ≥25 kg/m² to <30 kg/m²).59 However, this association was not apparent after adjustment for traditional cardiovascular risk factors of diabetes, hypertension, and dyslipidemia. A study of Korean men without diabetes or hypertension demonstrated a fourfold increase in the risk for CKD among those gaining >0.75kg/year, even with normal weight at baseline.60 Other studies have demonstrated elevated inflammatory markers associated with CKD in those with higher BMI.41,25 Finally a meta-analysis of 16 cohort studies of body weight and kidney disease demonstrated a higher risk among the overweight and obese, particularly in women.61 These conflicting data highlight a need for further study to this potential relationship between body weight and kidney disease risk.

OTHER FACTORS

Other potential risk factors associated with CKD include hyperuricemia,41,60 periodontal disease,23,60,61 lead exposure,48 and illicit drug use.60 Genetic studies have suggested apolipoprotein E variants are associated with progression of CKD in both whites and blacks,60 and they have identified the nonmuscle myosin heavy-chain type II isoform A (MYH9) gene in association with nondiabetic kidney disease in African Americans.2,52 The exact role and importance of these factors in initiating or sustaining renal damages are not yet clear and require additional study.

PATHOPHYSIOLOGY

As evidenced by the variety of initiation and progression factors, kidney damage can result from heterogeneous causes. Diabetic nephropathy is characterized by glomerular mesangial expansion; in hypertensive nephrosclerosis, the kidney’s arterioles have arteriolar hyalinosis; and renal cysts develop in polycystic kidney disease. Therefore, the initial structural damage may depend on the primary disease affecting the kidney. However, the majority of progressive nephropathies share a final common pathway to irreversible renal parenchymal damage and ESRD (Fig. 52–1).7 The key elements of this pathway are (1) loss of nephron mass, (2) glomerular capillary hypertension, and (3) proteinuria.

The exposure to any of the initiation risk factors can result in loss of nephron mass. The remaining nephrons hypertrophy to compensate for the loss of renal function and nephron mass.73 Initially, this compensatory hypertrophy may be adaptive. Over time, the hypertrophy can lead to the development of intraglomerular hypertension, possibly mediated by angiotensin II.74
Angiotensin II is a potent vasoconstrictor of both afferent and efferent arterioles, but it preferentially affects the efferent arterioles, leading to increased pressure within the glomerular capillaries and consequent increased filtration fraction. The development of intraglomerular hypertension usually correlates with the development of systemic arterial hypertension. High intraglomerular capillary pressure impairs the size-selective function of the glomerular permeability barrier, resulting in increased urinary excretion of albumin and frank proteinuria. Angiotensin II may also mediate renal disease progression through nonhemodynamic effects.

Proteinuria alone may promote progressive loss of nephrons as a result of direct cellular damage. Filtered proteins such as albumin, transferrin, complement factors, immunoglobulins, cytokines, and angiotensin II are toxic to kidney tubular cells. Numerous studies have demonstrated that the presence of these proteins in the renal tubule activates tubular cells, which leads to the upregulated production of inflammatory and vasoactive cytokines, such as endothelin, monocyte chemoattractant protein (MCP-1), and CCL5 [regulated upon activation, normal T-cell expressed and secreted (RANTES)]. Proteinuria is also associated with the activation of complement components on the apiical membrane of proximal tubules. Accumulating evidence now suggests that intratubular complement activation may be the key mechanism of damage in the progressive proteinuric nephropathies. These events ultimately lead to scarring of the interstitium, progressive loss of structural nephron units, and reduction in GFR.

**CLINICAL PRESENTATION**

CKD is often asymptomatic, and should be suspected in individuals with conditions such as diabetes, hypertension, genitourinary abnormalities, and autoimmune diseases. In addition, individuals of older age and those with a family history of kidney disease should be considered for CKD screening. Recommended screening studies include serum creatinine and GFR measurement, urinalysis, and/or imaging studies of the kidneys. A novel tool known as SCreening for Occult REnal Disease (SCORED) may also help to identify those with CKD in a cost-effective and noninvasive manner. This self-administered survey predicts that nearly 20% of individuals with all risk factors of diabetes mellitus, advanced age, hypertension, and cardiovascular disease will have an eGFR<60mL/min/1.73m². Abnormal elevations of serum creatinine, reflecting decreases in GFR, or presence of urinary or imaging study abnormalities are indications for a full evaluation of CKD. Furthermore, the rate of GFR loss can vary in CKD because of differences in the underlying disease process and extent of kidney damage, treatment responsiveness, and compliance with therapies.

**CLINICAL PRESENTATION OF CKD STAGES 1 TO 4**

### General
- CKD development and progression may be insidious in onset, often without noticeable symptoms. The diagnosis of CKD requires measurement of serum creatinine, estimation of GFR, and assessment of the urine (urinalysis) for protein and/or albumin excretion.
- CKD stages 3, 4, and 5 require further workup to identify the presence of CKD complications of anemia, cardiovascular disease, metabolic bone disease, malnutrition, and disorders of fluids and electrolytes.

### Symptoms
- Symptoms are generally absent in CKD stages 1 and 2 and may be minimal during stages 3 and 4. General symptoms associated with stages 1 to 4 include edema, cold intolerance, shortness of breath, palpitations, cramping and muscle pain, depression, anxiety, fatigue, and sexual dysfunction. The classic symptoms associated with stage 5 CKD are discussed in chapters 53 and 54.

**Signs**

- Cardiovascular-pulmonary: Edema and worsening hypertension, electrocardiographic evidence of left ventricular hypertrophy, arrhythmias, hyperhomocysteinemia, and dyslipidemia
- Gastrointestinal: Gastroesophageal reflux disease, weight loss
- Endocrine: Secondary hyperparathyroidism, decreased vitamin D activation, β2-microglobulin deposition, and gout
- Hematologic: Anemia of CKD, iron deficiency, and bleeding
- Fluid/electrolytes: Hyper- or hyponatremia, hyperkalemia, and metabolic acidosis

The NKF K/DOQI defines kidney damage in reference to the presence of clinical proteinuria, in addition to the GFR. Clinicians should be aware of the methods available to detect and interpret proteinuria and albuminuria (Table 52-3). In addition, Chap. 50 provides a detailed discussion of the relative merits of the various methods currently available for the detection of urinary protein.

- Patients with stage 1 or 2 CKD disease usually do not have any symptoms or metabolic derangements such as acidosis, anemia, and bone disease. In addition, the most common measure of impairment of kidney function, serum creatinine, may be only slightly elevated in these early CKD stages. Consequently, estimation of the GFR and assessment for urinary protein is imperative for recognition of early stages of CKD. Because the early stages of CKD are often undetected, the diagnosis requires a high level of suspicion for patients with chronic conditions such as hypertension and diabetes. Signs and symptoms associated with CKD become more prevalent in stages 3 to 5. Anemia, abnormalities of calcium and phosphorus metabolism (secondary hyperparathyroidism), malnutrition, and fluid and electrolyte abnormalities become more common as kidney function deteriorates (see Chap. 53).

### ANEMIA

Because the kidneys secrete 90% of the endogenous hormone erythropoietin, a hormone necessary for erythropoiesis, declining kidney function can lead to erythropoietin deficiency and anemia. The prevalence of anemia at specific stages of CKD is difficult to ascertain because of limited available data and use of various definitions. Estimates of anemia [defined as a hemoglobin of <13.5 g/dL (<135 g/L; <8.38 mmol/L) in men and <12 g/dL (<120 g/L; <7.45 mmol/L) in women] to occur in 20% of those with stage 1 to 3 CKD, almost 65% of those with stage 4 CKD, and in 75% of those with stage 5 CKD. African Americans were twice more likely to have anemia than whites and Hispanics. Anemia can lead to symptoms of fatigue, weakness, and shortness of breath. However, mild anemia, especially when present for a prolonged time period, can be asymptomatic. The NKF K/DOQI guidelines recommend evaluating hemoglobin levels in all patients with CKD, noting the increase in anemia prevalence beginning with stage 3. The treatment of anemia can improve or resolve symptoms and may help to stabilize kidney function. Chapter 53 discusses the management of anemia in CKD.

### CARDIOVASCULAR DISEASE

CKD is associated with a high rate of cardiovascular morbidity and mortality. An epidemiologic study of more than 300,000 individuals demonstrated a strong relationship between GFR and cardiovascular disease: The lower the level of GFR, the higher the incidence of cardiovascular events. In fact, individuals with stages 2 to 4 CKD were more likely to die from cardiovascular disease complications than to survive to the initiation of renal replacement therapy. A recent evaluation of a large database of over 400,000 individuals demonstrated a nearly twofold risk of cardiovascular death among those with CKD. Data from NHANES and KEEP also demonstrate a greater risk of myocardial infarction, stroke, and death among those with CKD. Interestingly, two other recent studies have demonstrated elevated cardiovascular risk among those with a CKD diagnosis based separately on reduced GFR or albuminuria. In both studies, those with diminished GFR were considered as a different population than those with only albuminuria, suggesting that reduced GFR and albuminuria may provide separate cardiovascular risk information. Consequently, monitoring for the presence or development of cardiovascular disease for patients with CKD is an important aspect of their care. Appropriate traditional and nontraditional cardiovascular risk factor assessments are necessary in the evaluation of the patient with CKD. Guidelines for the evaluation, monitoring, and treatment of cardiovascular diseases for patients with CKD have been published.

### DISORDERS OF CALCIUM AND PHOSPHORUS HOMEOSTASIS

Abnormalities in calcium and phosphorus metabolism typically occur in stages 3 to 5 CKD. Secondary hyperparathyroidism, however, can develop earlier despite normal serum calcium and phosphorus levels, at a GFR of 80 mL/min per 1.73 m² or below. Thus, to detect secondary hyperparathyroidism and limit the
bone complications, it is recommended that parathyroid hormone concentration, vitamin D levels, and calcium and phosphorus be monitored beginning in stage 3 CKD. Additional systemic benefits of correcting abnormalities in calcium, phosphorus, and parathyroid hormone may include cardiovascular risk reduction. A recent controlled study of 24 CKD patients reported reductions in urinary protein excretion and high-sensitivity C-reactive protein with paricalcitol treatment. Additionally, an uncontrolled study of 10 IgA nephropathy patients reported a 25% reduction in urinary protein after initiation of twice weekly calcitriol therapy to existing angiotensin converting enzymes inhibitors. These studies show preliminary data suggesting the need for more extensive evaluations regarding any protective role of vitamin D on kidney function decline. Chapter 53 discusses the management of bone disease caused by CKD.

MALNUTRITION

Anorexia and malnutrition are complications of CKD. Although there are limited definitions exactly at which stage malnutrition develops, the NKF K/DOQI guidelines recommend evaluating for signs of malnutrition when the GFR is lower than 60 mL/min per 1.73 m² (stages 3, 4, and 5). An investigation for malnutrition should include a dietary assessment for protein and calorie intake, serum albumin, and/or assessment of protein appearance in the urine (as a marker of protein intake). Chapter 149 discusses the interpretation of these tests, and Chap. 153 discusses nutritional recommendations for patients with CKD.

TREATMENT

Chronic Kidney Disease

GOAL OF THERAPY

The goal of therapy is to delay the progression of CKD, thereby minimizing the development or severity of associated complications including cardiovascular disease and ultimately limiting the progression to ESRD. Both nonpharmacologic and pharmacologic interventions are available to slow the rate of CKD progression and may also decrease the incidence and prevalence of ESRD.

In addition to pharmacologic therapy, the patient with CKD usually will benefit from modest dietary protein. The main purpose of pharmacologic therapy is to control the underlying conditions (such as diabetes mellitus and hypertension) that have incited kidney damage to prevent further loss of kidney function. Patients generally require a multimodality treatment approach irrespective of the cause of their kidney disease. Therapy with ACEIs and/or ARBs is a nearly universal key therapeutic component.

Nonpharmacologic Therapy

Dietary Protein Restriction Experimental studies of kidney disease in animals suggest that dietary protein restriction may delay the rate of progression of kidney function decline. This hypothesis was tested in humans in the MDRD study, a randomized, controlled trial that evaluated the benefits of dietary protein restriction and blood pressure reduction on the rate of CKD progression. Most enrolled subjects had nondiabetic kidney disease, and 24% of them had diagnosis of polycystic kidney disease. Subjects with moderate CKD (GFR of 25 to 55 mL/min per 1.73 m²) were randomized by dietary protein intake groups (1.3 g/kg per day or 0.58 g/kg per day), in addition to blood pressure grouping, for a total of four groups. Subjects with advanced CKD [GFR 13 to 24 mL/min per 1.73 m²] were randomized to a low-protein diet (0.58 g/kg/day) or a very-low-protein diet (0.28 g/kg/day) with a ketogenic acid supplement, in addition to blood pressure, also for a total of four groups. After a mean followup of 2.2 years, protein restriction failed to show a statistical benefit in slowing the progression of CKD in any of the study groups. However, a secondary analysis of the MDRD study was conducted and revealed that in those patients with a GFR of less than 25 mL/min per 1.73 m², a protein intake of 0.6 g/kg per day was significantly associated with a decreased rate of progressive renal disease. In addition, this analysis showed that the rate of progression to ESRD was significantly reduced by 41% for each 0.2 g/kg per day reduction in dietary protein intake. The discrepancy in results between the primary and secondary analyses can be explained by the different statistical methods used in each of the two analyses, in that the later analysis evaluated participants who were actually compliant with their dietary prescription. The most recent follow-up of the advanced CKD group found no difference in progression to kidney failure but perhaps suggested an increased risk of death in the very-low-protein group. However, data on protein intake at the time of follow-up was not available.

Because of concerns regarding the inadequate statistical power of individual studies, recent meta-analyses have been performed to determine the effect of protein restriction on the progression of CKD. The studies have had varying conclusions, although the reduction in loss of GFR was relatively nominal. The most recent randomized trial in diabetic nephropathy was not able to demonstrate renoprotection of a low-protein diet but, most importantly, noted the difficulty that patients had adhering to the requirements of a low-protein diet.

Thus, the available data suggest only a relatively small benefit from dietary protein restriction in CKD patients. Because low-protein diets may lead to malnutrition for patients with advanced CKD and those with nephrotic-range proteinuria, the NKF K/DOQI has advocated a dietary protein intake of 0.6 g/kg per day for patients with a GFR <25 mL/min per 1.73 m². Titration of protein intake up to 0.75 g/kg per day is suggested for patients who cannot achieve or maintain adequate nutritional status with the lower protein (0.6 g/kg per day) diet.

Smoking Cessation

Although the effectiveness of smoking cessation on limiting progressive CKD has not been prospectively evaluated, one study suggested that smoking cessation resulted in a protective effect against proteinuria and reduced GFR. This later study showed that although current smokers had a significantly higher albumin excretion (and reduced GFR) versus nonsmokers, those patients who quit smoking had a statistical association with only microalbuminuria. Based on the evolving data concerning the detrimental effects of smoking on the kidney and the well-documented associations with cardiovascular disease, the clinician should educate patients regarding this risk and institute appropriate therapeutic options, both nonpharmacologic and pharmacologic, for smoking cessation. These options are discussed in further detail in Chap. 75.

Pharmacologic Therapy

Guidelines for CKD treatment usually recognize the differences in pathogenesis and course of diabetic and nondiabetic CKD. Consequently, pharmacologic interventions are discussed separately for these conditions within this chapter. The major focus of this chapter is on the impact of ACEI and ARB therapies on progressive CKD. Pharmacologic therapies specific for glomerulonephritis are
discussed in Chap. 56, while therapies for the treatment of complications of kidney disease are covered in Chap. 53.

**Diabetic Chronic Kidney Disease**

- INTENSIVE INSULIN THERAPY

Several large prospective studies performed in the 1990s showed the benefits of blood glucose control in both the development and progression of microvascular complications. The largest of these studies, the DCCT enrolled 1,441 patients with type 1 diabetes mellitus who were randomized to conventional blood glucose control or to intensive glucose control. Conventional control consisted of up to two insulin injections per day guided by blood glucose levels. Intensive control consisted of three or more times daily injections or external insulin pump to a goal hemoglobin A1c <6.0% (<0.06). The main outcome measure of efficacy was retinopathy, a marker of microvascular disease often associated with diabetic nephropathy among individuals with type 1 diabetes mellitus. Roughly half of the patients had mild retinopathy. Intensive insulin control reduced the risk of new occurrences of retinopathy by 76% among those without baseline retinopathy and reduced the risk of progressive retinopathy by 54% among those with baseline retinopathy. Intensive therapy was also associated with a 39% reduction in the development of “microalbuminuria” (urinary albumin excretion ≥40 mg/day) and a 54% reduction in the development of “frank albuminuria” (urinary albumin excretion ≥300 mg/day) compared with conventional therapy. The beneficial effect of intensive therapy on the development of proteinuria persisted even 7 to 8 years after completion of the randomized phase of the DCCT. Individuals initially randomized to the intensive therapy had a 59% reduction in the development of new microalbuminuria, and 84% reduction in the development of albuminuria compared with the conventional group. In the intensive therapy group, follow-up after 30 years of diabetes demonstrated a lower cumulative incidence of diabetic nephropathy (9% vs 25%). However, at least one episode of hyperglycemia occurred in 65% of intensive insulin therapy patients as compared with 35% in the standard treatment group.

The Intensive Glucose Control Study of the United Kingdom Prospective Diabetes Study (UKPDS) also evaluated prevention of microvascular complications among individuals with type 2 diabetes mellitus. Individuals newly diagnosed with type 2 diabetes mellitus were randomized to intensive therapy [goal fasting plasma glucose of <108 mg/dL (<6 mmol/L)] or conventional therapy [goal fasting plasma glucose of <270 mg/dL (<15 mmol/L)] after 3 months of dietary counseling. Individuals in either group could use oral sulfonylureas or insulin. After 10 years of followup, the intensive group had an 11% reduction in median hemoglobin A1c and a 12% reduction in any diabetes-related end point compared with the conventional group. Most of the observed benefit was in a reduction in microvascular end points, primarily proliferative retinopathy.

The DCCT, the UKPDS, and their long-term follow-up provide support for reducing microvascular complications, including nephropathy, with intensive therapy for patients with type 1 and type 2 diabetes mellitus. Intensive therapy can include insulin or oral drugs but employs testing of blood sugar at least three times daily. Furthermore, goals of therapy included an A1c of <7% (<0.07) and preprandial plasma and peak postprandial blood glucose of 92 to 130 mg/dL (5.1 to 7.2 mmol/L) and <180 mg/dL (10.0 mmol/L), respectively. However, recent data suggest that more aggressive glycemic goals [Hgb A1c of <6.0% (<0.06)] may be associated with increased mortality. Clinician’s are encouraged to review Chap. 83 for a thorough review of dosing, monitoring, and goals of therapies to treat diabetes mellitus.

- OPTIMAL HYPERTENSION CONTROL

The Seventh Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure recommends a goal blood pressure of less than 130/80 mm Hg for patients with CKD. Elevated blood pressure is often more difficult to control for patients with CKD than for those with normal kidney function. Therefore, to achieve adequate blood pressure goals, three or more different blood pressure medications are usually required. Figure 52–2 depicts the proposed algorithm for the management of hypertension for people with CKD and diabetes. The selection of individual classes of drugs for limiting progression of CKD is presented in the following sections.

Reduction of blood pressure in type 1 and type 2 diabetic patients has been associated with lower rates of CKD progression. The UKPDS, a randomized trial of captopril or atenolol among 1,148 hypertensive type 2 diabetic patients, evaluated the effect of blood pressure reduction to a level of less than 150/85 mm Hg versus less than 180/105 mm Hg on macrovascular and microvascular outcomes. Reductions of 24% in diabetes-related end points, 32% in deaths related to diabetes, 44% in strokes, and 37% in microvascular end points were observed after a median follow-up of 8.4 years. The benefit of blood pressure control has been confirmed in subsequent studies of type 2 diabetic subjects with microalbuminuria. These seminal studies used either ACEI (Table 52–4) or ARB (Table 52–5) classes of drugs, which likely have nonhemo-dynamic beneficial effects on CKD progression, as discussed below, as well as blood-pressure-lowering effects. In type 1 diabetes with nephropathy, a rigorous blood pressure goal (MAP of <92 mm Hg) leads to decreased proteinuria.

Patients diagnosed with both hypertension and diabetes mellitus have been estimated to have up to a sixfold higher risk of developing ESRD than do those patients with diabetes mellitus alone. Adequate blood pressure control can reduce the rate of decline in GFR and the degree of albuminuria for hypertensive type 1 and type 2 diabetic patients. Although all interventions that reduce blood pressure have historically shown reductions in urinary albumin and protein excretion, the ACEIs were the first agents shown to reduce glomerular capillary pressure and volume, which have resulted in preservation of renal function in animal models and human studies. Table 52–6 summarizes the documented effects of the other various available antihypertensive agents on renal blood flow and GFR.

### Antihypertensive Drug Choice

Several studies have confirmed the beneficial effects of ACEIs on renal function for patients with and without diabetes and both ACEIs and ARBs remain the mainstay of therapy. Table 52–4 shows the results of the key studies that evaluated more than 100 diabetic subjects followed over 2 to 6 years. These studies show that the benefit of ACEI use in CKD is seen in both type 1 and 2 diabetic subjects, across different degrees of kidney damage (normoalbuminuria, microalbuminuria, frank proteinuria, and reduction in GFR), and are drug-class specific. These findings consistently support the role of ACEI therapy in the management of CKD. It is customary to begin at low doses and increase the dose at 4-week intervals to control the level of proteinuria. The dose is usually increased until proteinuria is reduced by 30% to 50% or the development of side effects such as elevations in serum creatinine or potassium occurs.

A meta-analysis that pooled several of the small and large randomized, controlled studies showed beneficial effects of ACEI therapy on diabetic nephropathy. Progression to proteinuria was reduced by 65% for patients with diabetes mellitus and microalbuminuria, and progression of nephropathy (doubling of serum creatinine) was reduced by 40% for patients with overt proteinuria (comprised of 30% diabetics and 70% nondiabetics) (Fig. 52–3). However, a meta-analysis of 127 studies with more than 30,000 subjects suggests...
that the benefit of ACEIs and ARBs over other pharmacologic agents is related to blood pressure attained during the study rather than to special properties of the ACEI or ARB (e.g., antiproteinuric effects).\textsuperscript{113} The ARBs have also been shown to slow the progression of diabetic kidney disease.\textsuperscript{122-125} Table 52–5 summarizes data from several key studies (with at least 100 patients) evaluating ARB efficacy in type 2 diabetes. All patients in these trials had at least a level of proteinuria consistent with microalbuminuria and all were hypertensive. With the exception of one, the studies were of a sufficiently long duration to determine the beneficial effects of ARBs on nephropathy. Of note, the beneficial effect of delaying the onset of diabetic nephropathy was significant in type 2 diabetic patients who received irbesartan 300 mg daily for up to 2 years.\textsuperscript{123} A similar trend (although not statistically significant) was observed in those subjects who received a lower dose of irbesartan (150 mg daily). Currently, the data show efficacy of both ACEIs and ARBs in type 2 diabetes, whereas only ACEIs have been adequately evaluated for patients with type 1 diabetes. Although no data exist comparing ACEIs and ARBs in head-to-head trials in type 2 diabetes, in practice these agents are used somewhat interchangeably. ACEIs are typically started as first line with a change to an ARB if not tolerated.

The lack of response among some patients to ACEI or ARB therapy with regards to blood pressure or proteinuria may be due to aldosterone escape in renin-angiotensin-aldosterone system blockade. Type 2 diabetic subjects with nephropathy who had increased aldosterone plasma levels during a mean 35-month treatment with losartan had a faster decline in the rate of GFR compared with those without aldosterone escape.\textsuperscript{126} With the thought that further aldosterone blockade may improve outcomes, combination therapy with both ACEIs and ARBs has been investigated in both studies and subsequent metaanalyses.\textsuperscript{135-138} In summary, these studies demonstrate a greater reduction in proteinuria with the combination of these agents, with some studies demonstrating a trend to higher serum potassium and serum creatinine concentrations. Unfortunately, none of these are of sufficient duration to determine if the reduction in proteinuria translates to preservation of renal function. It was recently suggested that polymorphisms in the cytochrome P450 (CYP2C9) drug metabolizing gene may result in less favorable therapeutic response to the ARB losartan.\textsuperscript{139} The Arg144Cys and Ile359Leu polymorphisms are reported to reduce CYP2C9 activity,\textsuperscript{140,141} and this may result in formation of metabolites with less pharmacological activity than E-3174. A recent study has raised concerns with the use of combination ACEI/ARB. The Ongoing Telmisartan Alone and in Combination
with Ramipril Global Endpoint Trial (ONTARGET) randomized 25,620 patients with established atherosclerotic vascular disease or diabetes with end-organ damage to telmisartan, ramipril, or a combination of the two drugs. The composite outcome of any dialysis, renal transplantation, doubling of serum creatinine, or death occurred more frequently for patients receiving combination treatment than in either of the two other groups, despite a lower degree of albuminuria and less progression to micro- or macroalbuminuria. These findings have led some to advise against the combination of these two agents, however, criticisms of the study have argued that these findings cannot be extrapolated to those with proteinuric renal disease as only 4% of patients in the study had overt proteinuria. Combination therapy with ACEI and ARB likely does have a role for patients with diabetic nephropathy with overt proteinuria and is being evaluated more closely in an ongoing randomized double-blind multicenter clinical trial of Veterans Administration patients (VA NEPHRON D).

FIGURE 52-3. Therapeutic strategies to prevent progression of renal disease in diabetic individuals. (Blood glucose of 70 to 120 mg/dL corresponds to 3.9 to 6.7 mmol/L) (A) Relative risk for developing microalbuminuria with 95% confidence intervals (CIs) in each study, and the aggregate relative risk with 95% CIs for all studies (N = 642 with diabetes). (B) Relative risk for doubling serum creatinine concentration or development of ESRD with 95% CIs in each study, and aggregate relative risk with 95% CIs for all studies (N = 1,277; 479 with diabetes). (ACE, angiotensin-converting enzyme.) (Reprinted from Am J Kidney Dis, Vol. 35(4), Khirsagar AV, Joy MS, Hogan SL, Falk RJ, Colindres RE. Effect of ACE inhibitors in diabetic and nondiabetic chronic renal disease: a systematic overview of randomized placebo-controlled trials, pages 695–707, Copyright © 2000, with permission from Elsevier.)

Studies suggest that no individual ACEI drug is truly superior to any other ACEI, and the same holds true for ARBs. For patients with hypertension, the primary goal is to optimally treat the blood pressure to target, and the secondary goal is to control proteinuria. For normotensive patients with microalbuminuria, one should titrate the ACEI/ARB to reduce the degree of microalbuminuria. However, patients with hypertension and proteinuria may still exhibit side effects associated with blood pressure lowering, and dosages should be titrated to the maximum reduction of proteinuria without reducing blood pressure to a level associated with adverse events including renal function compromise. Patients should be initiated on the lowest possible dose of ACEI/ARB and titrated to blood pressure control and proteinuria reduction. A specific recommendation regarding the dose to initiate therapy with a specific ACEI/ARB has not been established; consequently, the lowest recommended dose for the management of hypertension may be appropriate until such information is available. In addition, one needs to consider the presence of other concomitant diseases and past history of treatment, as well as any side effects demonstrated with particular agents. Generally, ACEIs are more cost-effective than ARBs because of the availability of generic formulations, and individual patient insurance coverage should be reviewed by the

CLINICAL CONTROVERSY

ACEI and ARBs have been advocated for treatment of hypertension in CKD for the reduction of proteinuria. Early studies suggested that a combination of ACEI and ARB may have additional benefit; however, recent data suggest that the combination may be associated with a higher incidence of adverse outcomes including frequent hyperkalemia and need for acute dialysis. However, many would still advocate for combined ACEI and ARB therapy for patients with overt proteinuria.
clinician. If patients exhibit adverse effects such as cough and/or hyperkalemia, a switch to an ARB may be appropriate.

Because the clearance of all ACEIs (with the exception of fosinopril) is reduced in CKD, it is prudent to commence therapy at lower initial doses and subsequently titrate to achieve the optimal therapeutic effects and minimize potential toxicity. The antiproteinuric effects of ACEIs/ARBs are not necessarily attained at the same doses as the antihypertensive effects. Thus patients who have reached their blood pressure goals may require further dosage adjustments to achieve maximal reductions in urinary protein excretion. Serum potassium needs to be monitored when initiating therapy or changing doses with ACEIs or ARBs, especially when patients are concurrently receiving drugs that may increase the risk of hyperkalemia, such as nonsteroidal antiinflammatory agents. Chapter 19 has a thorough discussion of dose, dose titration, monitoring, and adverse effects of ACEIs and ARBs.

As noted above, the concept of aldosterone escape has led to the search for other methods in which to further suppress the renin-angiotensin-aldosterone system (RAAS) in an effort to improve renal outcomes. Spironolactone, a mineralocorticoid receptor blocker, can be added to ACEI/ARB therapy with careful monitoring since these patients would be at risk for hyperkalemia. An important systematic review of 15 studies including 8 randomized control trials evaluating spironolactone added to ACEI and/or ARB demonstrated a further reduction in proteinuria ranging from 15% to 54% with minimal hyperkalemic events. Long-term data and information on preservation of renal function are still lacking, however. The newest agent of potential benefit is aliskiren, a direct renin inhibitor. This agent has been evaluated in three trials, two in combination with an ARB and one in combination with a diuretic. Proteinuria was reduced in all of these studies although data regarding long-term benefit are lacking. The exact role of both these agents—whether to be used alone, with an ACEI or ARB, or added to ACEI/ARB combination—is still to be determined.

Some calcium channel blockers (CCBs) decrease glomerular injury without negatively changing renal hemodynamics. The postulated mechanisms for this decrease in renal injury include suppression of glomerular hypertrophy, inhibition of platelet aggregation, and decrease in salt accumulation. Although the data regarding dihydropyridine CCBs do not suggest any beneficial effects beyond those attributable to reducing blood pressure, there is some suggestion that the nondihydropyridine agents (diltiazem and verapamil) may have beneficial effects on proteinuria, although not as profoundly as ACEIs. These agents are used occasionally in combination with ACEIs or ARBs, although data are limited to support this. In general, nondihydropyridine CCBs are used as second-line antiproteinuric drugs when ACEIs or ARBs are not tolerated. Efonidipine and manidipine, novel dihydropyridine CCBs that affect T-type calcium channels rather than L-type calcium channels, reduce intraglomerular pressure and may have antiproteinuric effects as well. However, these drugs are not presently available in the United States, and how to best utilize these agents is not yet known.

### Nondiabetic Chronic Kidney Disease

#### ANTIHYPERTENSIVE AGENTS

- **Reduction of blood pressure is key to decreasing cardiovascular and renal sequelae.** However, all antihypertensive agents are not equal in their ability to preserve kidney function despite similar efficacy in terms of blood pressure reduction. Among the different antihypertensives available, ACEIs and ARBs are currently also considered the first choice for patients with nondiabetic CKD because they reduce intraglomerular pressure. Several short- and long-term clinical trials have assessed the effect of ACEIs on renal function for patients without diabetes; Table 52–7 summarizes these trials. These studies vary in length from 12 weeks to 7 years, and

several enrolled a small number of subjects. Most patients had nephropathy associated with proteinuria and advanced CKD. Significant reductions in the risk of doubling serum creatinine, requirement for dialysis, and/or proteinuria were demonstrated for patients receiving the ACEIs. These studies and the summary results of a meta-analysis revealed that ACEIs conferred a 40% reduction in the risk of developing ESRD or doubling of serum creatinine for patients with overt proteinuria (>300 mg protein per 24 hours) and renal disease of various etiologies (see Fig. 52–3).132 However, a meta-analysis failed to show a significant benefit of ACEI and/or ARBs over other antihypertensive agents in CKD progression.133 A post hoc analysis of the African American Study of Kidney Disease and Hypertension (AASK), which evaluated two different blood pressure targets and three different treatment regimens in subjects with a GFR between 20 and 65 mL/min per 1.73 m² showed that the change in the level of proteinuria over 6 months of treatment predicted the progression of hypertensive CKD.134 In addition, a post hoc analysis of the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), where hypertensive subjects were randomized to chlorthalidone, amldipine, or lisinopril for a mean of 4.9 years, revealed similar incident rates of ESRD in the three treatment groups irrespective of the cause of renal disease.135 Therefore, although the drug class versus absolute blood pressure reduction is an evolving area of investigation, current treatment guidelines recommend use of ACEI or ARBs in subjects with CKD.

The ARBs, although evaluated to a lesser extent than ACEIs, appear to have similar efficacy in terms of kidney protection for patients with several forms of glomerulonephritis (Table 52–8).136,139 Proteinuria reduction on the order of 25% to 47% was shown with ARB therapy. However, these studies employed small numbers of patients with short follow-up time frames as compared with studies in diabetic patients. Despite these limitations, most clinicians use either ACEI or ARB therapy as the standard of care for patients with nondiabetic CKD and proteinuria. The combination use of ARBs with ACEIs, similar to data in diabetic kidney disease, results in a greater decrease in proteinuria than that seen with either agent alone.140 The Combination Treatment of Angiotensin-II Receptor Blocker and Angiotensin-Converting Enzyme Inhibitor in Non-diabetic Renal Disease (COOPERATE) study prospectively evaluated the use of losartan 100 mg daily alone, trandolapril 3 mg daily alone, or the combination of the two in 336 patients with nondiabetic kidney diseases. The primary end point, time to doubling of serum creatinine or ESRD, was observed in 11% of combination therapy patients and in 23% of each of the single-agent treatment groups.141 However, this study has drawn several criticisms.142,143 In light of the ONTARGET study findings above,144 combination therapy may be dangerous and perhaps is best used in the setting of overt proteinuria and with close supervision. The selection of ACEIs versus ARBs in the control of proteinuria in nondiabetic kidney disease is essentially predicated on cost of therapy, patient tolerance, and clinician preference. As with diabetic kidney disease, modulation of RAAS with mineralocorticoid blockers, such as spironolactone,147 and perhaps the direct renin inhibitor, aliskiren, may have a role in kidney disease with overt proteinuria.

The CCBs are also effective treatments for hypertension for patients with nondiabetic CKD. However, as was mentioned previously, only the non-dihydropyridine CCBs have been studied and shown to reduce the rate of decline of kidney function. There are currently no data to suggest that higher doses of non-dihydropyridine CCBs are needed to elicit a reduction in proteinuria as compared with a reduction in blood pressure. The role of dihydropyridine T-type CCBs remains uncertain.

Although diuretics are commonly used to treat fluid overload and hypertension for patients with CKD, there are minimal data to suggest any renal protection in terms of proteinuria regression or a reduction in the rate of progression. A single randomized, controlled trial has demonstrated an additive benefit of hydrochlorothiazide, a thiazide diuretic, to an ACEI regimen in reducing proteinuria in nondiabetic proteinuric kidney disease.148 Chapter 58 addresses the use of diuretics for managing volume overload. Other available antihypertensive agents are used to control blood pressure in patients with kidney disease. Additional central and peripherally acting antihypertensive agents can be used for patients with CKD. One must consider the need for dosage reductions caused by decreases in GFR for drugs that are excreted by the kidneys and/or supplemental doses as a consequence of dialysis removal of hydrophilic β-blockers such as nadolol, acebutolol, and atenolol.

Regardless of the treatment regimen, hypertension should be treated to the currently accepted targets for patients with CKD. If proteinuria is present, the use of ACEIs, ARBs, and possibly non-dihydropyridine CCBs may be superior to conventional agents in decreasing proteinuria and glomerular hypertension.

As precipitous reductions in blood pressure may be deleterious to kidney function for patients with underlying CKD, blood pressure targets in these patients should be achieved over several weeks to allow the kidney to adapt to reduced perfusion pressures.149 Typically there is an acute but sustained reduction in GFR of approximately 25% to 30% within 3 to 7 days after initiation of ACEI therapy as a result of a reduction in intraglomerular pressure.150 If a sustained increase in the serum creatinine by more than 30% after ACEI therapy initiation is observed, reduction of the dose or even discontinuation of ACEI therapy should be strongly considered (see Chap. 55). It is necessary to realize that although ACEI therapy may be effective in reducing the rate of nephropathy progression, one needs to consider their propensity for hyperkalemia and potential for acute GFR reduction especially for patients who already have compromised GFR.

FSGS, focal segmental glomerulosclerosis; GFR, glomerular filtration rate; UPE, urinary protein excretion.
Some clinicians fail to prescribe ACEI or ARB medications when the GFR is less than 20 to 30 mL/min per 1.73 m² because they fear the patient may develop a further elevation in serum creatinine, whereas other clinicians prescribe these medications and evaluate serum creatinine closely after therapy initiation and dosage increases.

Other Interventions to Limit Disease Progression

Other interventions such as lipid-lowering regimens and anemia management have been suggested to slow the progression of CKD.

Hyperlipidemia Treatment

Although several drugs are available for lipid lowering, the β-hydroxy-β-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins, and gemfibrozil have been most often used in dyslipidemic patients with CKD with and without proteinuria. The primary goal of treatment is to decrease the risk for progressive atherosclerotic cardiovascular disease. Additionally, a prior meta-analysis of 13 studies of lipid-lowering agents also showed a reduction in the rate of CKD progression by 0.156 mL/min per month. Mechanisms for this effect are unknown, but statins may reduce proteinuria, inflammation and fibrosis. In animal models of hyperlipidemia and kidney disease, lipid-lowering agents can decrease the extent of glomerular injury. Recent clinical data have provided less certainty. A post hoc analysis of the ALLHAT demonstrated no difference in ESRD rates among those treated with pravastatin versus those treated with usual care. A Cochrane systematic review demonstrated a decline in proteinuria and all-cause cardiovascular mortality but no attenuation of the decline of renal function. However, this would not preclude appropriate treatment of hyperlipidemia. Additional therapies that show favorable benefits on lipids are cholestyramine, carnitine, fish oil, low-molecular-weight heparins, and exercise. The National Cholesterol Education Program III and NKF K/DOQI guidelines should be consulted for a thorough review of lipid reduction and cardiovascular disease for patients with CKD. Therefore, treatment of lipid abnormalities for patients with CKD may have a beneficial effect on slowing the rate of progression of the kidney disease.

Anemia Treatment

Prolonged anemia is associated with left ventricular hypertrophy and heart failure. It has been suggested that anemia may increase the rate of CKD progression. Researchers have coined the phrase “cardiorenal anemia syndrome” to describe the interrelationship between anemia, heart failure, and CKD. Tissue hypoxia associated with anemia could be a stimulus for continued renal injury in those with stages 3 to 5 CKD. Although, at present, no definitive studies have been performed, some have hypothesized that the treatment of heart failure and anemia may reduce the progression of both heart failure and CKD. Chapter 53 discusses anemia as a complication of CKD.

PHARMACOECONOMIC CONSIDERATIONS

The financial and societal costs of the care of individuals with CKD are disproportionately high. Excluding those with ESRD, patients with CKD comprise less than 10% of the Medicare population, yet account for nearly 28% of Medicare expenditures or over $57 billion. These statistics suggest that the spectra of CKD is responsible for nearly one third of total Medicare expenditures.

There have been several evaluations of the potential pharmacoeconomic impact of screening for microalbuminuria in various populations. Generally speaking, the cost-effectiveness of screening is most apparent when targeted to high-risk populations including those with hypertension or diabetes or those over the age of 60. When applied to diabetes, screening actually appears to have associated cost savings. When compared with other conventional measures, such as screening for cervical cancer, screening for proteinuria in appropriate populations is similar or more favorable. Intensive management of diabetes and hypertension beyond screening also appear to cost-effective. As a caveat, these analyses employ simulated models whose results remain to be prospectively confirmed.

With regard to choice of pharmacologic agent, the majority of focus has been on agents employed in RAAS blockade. Both ARBs and ACEIs have been evaluated in the setting of diabetic kidney disease and appear to be favorable from the standpoint of cost and quality-adjusted life years gained. ACEIs have demonstrated similar cost benefit in nondiabetic kidney disease. One study provides data to suggest that even the more novel and expensive direct renin inhibitor, aliskiren, may have a beneficial cost profile in hypertensive diabetics with proteinuria. In summary, screening and optimal therapy with intensive glycemic control and RAAS blockade may limit progression to ESRD and death with reasonable costs to society.

CONCLUSIONS

DIABETICS

Based on the available clinical and experimental data, pharmacologic interventions can help to limit the progression of CKD in diabetic patients. Figure 52–4 summarizes these interventions. All patients with type 1 diabetes for a duration of more than 5 years and all type 2 diabetics should be screened yearly for microalbuminuria (urinary albumin excretion or urinary albumin-to-creatinine ratio). Blood glucose should be maintained within or close to the normal range by frequent insulin doses or by using a continuous subcutaneous insulin infusion while minimizing the risk of hypoglycemia by frequent blood glucose monitoring. ACEI therapy should be initiated in normotensive and hypertensive type 1 or type 2 diabetic patients with persistent microalbuminuria (30 to 300 mg/day) or overt albuminuria (greater than 300 mg/day). ACEIs should be titrated every 1 to 3 months to achieve a maximal reduction in urinary albumin excretion. Within 1 week of initiating or increasing the dose of an ACEI, serum creatinine and potassium should be evaluated to detect abrupt reductions in GFR or development of hyperkalemia. ARBs should be considered as another first-line therapy for type 2 diabetic patients for the reduction of persistent proteinuria or albuminuria. A nondihydropyridine CCB may be an effective secondary alternative agent for patients who are unable to tolerate either an ACEI or an ARB. A combination of an ACEI with an ARB may result in a greater reduction in proteinuria or albuminuria than either agent alone and thus may be a therapeutic alternative for patients who are not maximally responding to single-agent therapy. Addition of an aldosterone receptor blocker may be considered in subjects with documented aldosterone escape. Direct renin inhibition represents a novel approach whose role is still to be determined.

NONDIAETIC PATIENTS

Figure 52–5 summarizes therapeutic interventions for nondiabetic patients with CKD. Nutritional management should be monitored frequently, regardless of the amount of protein intake prescribed,
**CHAPTER 52**

**Lifestyle modifications per JNC VII**

- Dietary restriction of cholesterol
- Weight reduction
- Exercise

**Pharmacologic lipid-lowering agents**

- Diabetes
- Reduced blood pressure <130/80

**Proteinuria**

- Screen for UAE once a year

- Microalbuminuria × 2 (30–300 mg/day)
- Albuminuria × 1 (>300 mg/day)

- Initiate ACEI (or ARB) therapy

- Titrate therapy to achieve maximal effect on UAE

- Monitor serum K⁺, Scr, and UAE

**Poor metabolic control**

- Intensify glycemic control (Goal: normal fasting blood glucose 70–120 mg/dL)

- Multiple daily insulin injections or Continuous SC insulin infusion by pump

- Minimize hypoglycemia

  - • Monitor blood glucose up to 4 times per day

**Dietary protein restriction**

- 0.6 g/kg/day

**Microalbuminuria × 2 (30–300 mg/day)**

**Albuminuria × 1 (>300 mg/day)**

**FIGURE 52-4.** Therapeutic strategies to prevent progression of renal disease in diabetic individuals. (ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; UAE, urinary albumin excretion; SC, subcutaneous).

**FIGURE 52-5.** Therapeutic strategies to prevent progression of renal disease in nondiabetic individuals. (ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; GFR, glomerular filtration rate; CLcr, creatinine clearance; MAP, mean arterial pressure; Scr, serum creatinine.)
to avoid malnutrition. Based on the results of the MDRD study, a low-protein diet is of variable benefit for patients with moderate kidney dysfunction [GFR 25 to 55 mL/min per 1.73 m²]. Thus it is probably reasonable to prescribe a standard-protein diet unless the patient develops rapid progression of their kidney disease. For patients with severe kidney dysfunction, as defined by the MDRD study as a GFR of 13 to 24 mL/min per 1.73 m², a low-protein diet of 0.6 g/kg per day may reduce the rate of decline in kidney function, the time to reach end-stage kidney disease, and the onset of uremic symptoms.36

Blood pressure control should target normotensive levels of less than 130/80 mm Hg for patients with CKD.36 For patients with proteinuria above 3 g/day and CKD, an ACEI or ARB is still considered to be first-line therapy. Hyperlipidemia should also be treated to decrease cardiovascular risks.

As kidney function decreases and subjects approach CKD stage 4, the patient should begin to get prepared for renal replacement therapy: Hemodialysis, peritoneal dialysis, and renal transplantation need to be discussed (see Chapters 54 and 98). Early referral to a nephrologist or other clinician specializing in the care of patients with progressive CKD may allow the proper dialysis vascular access placement and the evaluation for uremia symptoms and may allow for identification and treatment of the complications including anemia and metabolic abnormalities.38

REFERENCES

The number of patients with chronic kidney disease (CKD) is increasing, and it is expected that the number of patients with end-stage renal disease (ESRD) will exceed 780,000 by the year 2020.

Common complications of stages 4 and 5 CKD include anemia, CKD–mineral and bone disorder (MBD) and renal osteodystrophy, fluid and electrolyte abnormalities, metabolic acidosis, and malnutrition.

Anemia of CKD, which is primarily caused by a deficiency in the production of endogenous erythropoietin by the kidney, is a common complication observed in patients with stages 4 and 5 CKD.

CKD-MBD and renal osteodystrophy are common in patients with CKD and contribute to extravascular calcifications and an increased risk of cardiovascular mortality.

Cardiovascular complications are prevalent in the CKD population and are the leading cause of mortality in patients with ESRD. Thus at the initiation of dialysis, all ESRD patients should be assessed for cardiovascular disease, which includes assessment for coronary artery disease, cardiomyopathy, valvular heart disease, cerebrovascular disease, and peripheral vascular disease in addition to screening for both traditional and nontraditional cardiovascular risk factors.

The management of CKD and the associated secondary complications should be initiated prior to development of ESRD.

Guidelines by the National Kidney Foundation Kidney Disease/Dialysis Outcomes Quality Initiative (NKF-K/DOQI) and Kidney Disease: Improving Global Outcomes (KDIGO) provide information to assist health care providers in clinical decisions and the design of appropriate therapy to manage complications.

Patient education plays a critical role in the appropriate management of patients with stage 4 or 5 CKD and related complications. A multidisciplinary team structure is a rational approach to provide this education and effectively design and implement the extensive nonpharmacologic and pharmacologic interventions required.

Management of anemia includes administration of erythropoietin-stimulating agents (ESAs) (epoetin alfa and darbepoetin alfa) and regular iron supplementation (oral or intravenous administration) to achieve a target hemoglobin of 11 to 12 g/dL (110–120 g/L; 6.83–7.45 mmol/L). There is now evidence indicating a higher risk of cardiovascular events when hemoglobin is targeted to greater than 12 g/dL (120 g/L; 7.45 mmol/L).

Management of CKD-MBD includes dietary phosphorus restriction, prudent use of phosphate-binding agents, vitamin D, and calcimimetic therapy.

The clinical syndrome that develops insidiously as kidney function declines to stages 4 and 5 chronic kidney disease (CKD), begins with nonspecific symptoms such as nausea and vomiting, which become progressively worse as the glomerular filtration rate (GFR) drops below 15 mL/min/1.73 m² (0.14 mL/s/m²). At this level of GFR renal replacement therapy, either dialysis (see Chap. 54) or transplantation (see Chap. 98), is indicated. The patient with stage 5 CKD requiring chronic dialysis or renal transplantation is said to have end-stage renal disease (ESRD). In this chapter, ESRD refers specifically to patients who are receiving chronic dialysis.

The staging system for CKD was primarily designed to help clinicians identify individuals in need of appropriate interventions to delay progression of CKD, as discussed in Chapter 52. Often complications of CKD are unrecognized or are inappropriately managed, and for many patients this contributes to significant morbidity, premature mortality, or a poor prognosis by the time they reach ESRD. The most frequent complications of CKD include fluid and electrolyte abnormalities, anemia, CKD-related mineral and bone disorder (CKD-MBD) and renal osteodystrophy, hypertension, hyperlipidemia, and metabolic acidosis. Miscellaneous complications resulting from the effects of CKD on other organ systems also occur. Table 53–1 lists other complications of CKD that are not specifically covered in this chapter. Cardiovascular disease is also common in patients with CKD and requires early and aggressive intervention. This chapter discusses the epidemiology of CKD and the pathophysiology and pharmacotherapeutic management of the complications and comorbidities that occur frequently in adult patients with stage 4 and 5 CKD.

increased. The 2009 report of the United States Renal Data System (USRDS), indicates that in 2007, the latest year for which data are available, a total of 111,000 new cases of ESRD were reported (incidence) and the number of individuals with ESRD (prevalence) as of the end of 2007 was 527,283, including 368,544 patients on dialysis and 158,739 with a functioning kidney after transplantation. Incidence rates of ESRD are higher in African Americans (3.7 times greater) and Native Americans (1.8 times greater) compared with whites, a trend that has persisted over the last decade. The incidence in Hispanics is 1.5 times greater than that observed in non-Hispanics. The incident rate has also increased dramatically in patients 65 years of age and older over the last decade and the prevalence has increased 24% since 2000. Although the overall number of patients with ESRD is substantial now, it is projected that by the year 2020 the number will exceed 780,000 patients, with the majority of cases attributable to diabetes. Total Medicare costs for ESRD in 2007 were approximately $24 billion, a 6.1% increase from the previous year, which accounted for 5.8% of the total Medicare budget in 2007.

The mortality rate in the ESRD population increases substantially with age and is much greater than age-matched individuals in the general population for every age group. In fact, ESRD patients have a mortality rate 7 to 8.5 times higher than age-matched individuals without kidney disease. Associated predictors of mortality and hospitalization in hemodialysis patients include decreased serum albumin, elevated phosphorus, low hemoglobin level, catheter use for dialysis access, and the presence of comorbidities, such as diabetes and cardiovascular disease. The association of mortality with these factors highlights the need to address complications as soon as they are detected, ideally prior to development of ESRD.

CKD was identified as one of the public health priorities for the nation in the Healthy People 2010 and the Healthy People 2020 disease prevention and health promotion objectives. The proposed goals of this 2020 initiative as it relates to CKD are as follows: (a) reduce the rate of new cases of ESRD, (b) reduce deaths in persons with ESRD, (c) increase the proportion of CKD patients receiving care from a nephrologist at least 12 months before the start of renal replacement therapy, (d) reduce kidney failure due to diabetes, (e) increase the proportion of persons with diabetes and CKD who receive recommended medical evaluation and who receive medical treatment with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers, (f) improve cardiovascular care in persons with CKD, (g) reduce the percentage of the U.S. population with CKD, (h) reduce the death rate among people with CKD, and (i) increase the percentage of persons with CKD who know they have impaired renal function.

**ETIOLOGY**

Many clinical conditions and diseases lead to progressive kidney damage and ESRD (see Chaps. 52 and 56). Diabetes mellitus continues to be the leading cause of CKD and ultimately of ESRD in the United States, accounting for 54% of new ESRD cases in 2007. Hypertension, as the second leading cause of ESRD in the United States, accounts for approximately 33% of new cases of ESRD. Glomerulonephritis, which includes a wide variety of lesions caused by immunologic, vascular, and other idiopathic diseases (see Chap. 56) is the third leading cause of ESRD in the United States. Other diseases and conditions causing CKD are cystic kidney disease, Wegener granulomatosis, vascular diseases, and acquired immunodeficiency syndrome (AIDS) nephropathy.

**PATHOPHYSIOLOGY**

Progression of CKD to ESRD occurs over years to decades in the majority of cases, with the precise mechanism of kidney damage dependent on the etiology of the disease (see Chaps. 52 and 56). The consequences and complications of marked reductions in kidney function are fairly uniform irrespective of the underlying etiology. The mechanisms of progression of CKD and measures to delay progression are essential elements for primary care clinicians to consider as they design intervention strategies for their patients. Those clinicians who care for patients with ESRD or stages 4 and 5 CKD must also have a clear understanding of the pathogenesis, clinical presentation, and management strategies for secondary complications and comorbidities to improve quality of care and outcomes.

No single toxin is responsible for all of the signs and symptoms of uremia observed in patients with stage 4 or 5 CKD. Accumulation of one or several of these known and potential toxins may be the result of increased secretion, as with the biologically active substances such as parathyroid hormone (PTH) and atrial natriuretic peptide; decreased clearance because of reduced metabolism within the kidney for compounds such as PTH, gastrin, growth hormone, glucagon, somatostatin, prolactin, calcitonin, and insulin; and/or decreased renal clearance of metabolic by-products of protein metabolism. The buildup of these uremic toxins ultimately results in altered organ and immune function and leads to a myriad of secondary complications.

1. Altered fluid and electrolyte homeostasis, metabolic acidosis, anemia of CKD, CKD-MBD and renal osteodystrophy, and cardiovascular disease are among the common complications associated with a substantial decline in GFR. The pathophysiology of these complications is described here.

**FLUID AND ELECTROLYTE ABNORMALITIES**

**Sodium and Water**

In persons with normal kidney function, sodium balance is maintained at a sodium intake of 120 to 150 mEq/day (120–150 mmol/day). The fractional excretion of sodium (FE\(\text{Na}\)) ranges from approximately 1% to 3% (see Chap. 58 for more information). Water balance is also maintained with a normal range of urinary osmolality of 50 to 1,200 mOsm/kg (50–1,200 mmol/kg); average range 500–800 mOsm/kg [500–800 mmol/kg]. In most
individuals with CKD and stable kidney function, total body sodium and water increase modestly, but may not be clinically obvious. Free water clearance is generally maintained until the more advanced stages of CKD when patients have a reduced ability to concentrate or dilute their urine. In patients with severe CKD (stages 4 and 5), serum sodium concentration is generally maintained as the result of an increase in \( FE_{\text{Na}} \) by as much as 30%, but results in a volume-expanded state. Significant sodium retention is more common when the GFR is less than 10 mL/min/1.73 m\(^2\) (0.10 mL/s/m\(^2\)). Volume overload with pulmonary edema can result, but the most common manifestation of increased intravascular volume is hypertension, which may further contribute to progressive kidney damage.

Individuals with CKD may also have impaired ability to conserve sodium and water. As a result they are prone to develop prerenal acute kidney injury when conditions of volume depletion occur (e.g., vomiting, blood loss, diarrhea, etc.). Thus \( FE_{\text{Na}} \) and urine osmolality may be less useful in patients with advanced CKD who develop acute on chronic CKD to differentiate prerenal from an intrinsic acute kidney injury.

**Potassium Homeostasis**

Serum potassium is freely filtered at the glomerulus, reabsorbed in the proximal tubule and loop of Henle, and actively secreted into the urine at the cortical collecting duct. The kidneys normally excrete 90% to 95% of the daily potassium dietary load. The fractional excretion of potassium (\( FE_{\text{K}} \)) is approximately 25% (0.25) (see Chap. 60). Normally only 5% to 10% of ingested potassium is excreted through the gut. Potassium homeostasis is also maintained by shifting extracellular potassium intracellularly immediately following ingestion of a potassium load. In patients with CKD, potassium balance is maintained by an increase in distal tubular potassium secretion in which aldosterone plays an important role; \( FE_{\text{K}} \) can increase to as high as five times normal. Thus the serum potassium concentration is usually maintained in the normal range until the GFR is less than 20 mL/min/1.73 m\(^2\) (0.19 mL/s/m\(^2\)), at which point mild hyperkalemia is likely to develop. Mild elevations are observed in stage 3 CKD, but more significant (and life-threatening) elevations are likely to be observed in those with stage 4 and 5 CKD. A significant increase in potassium secretion by the colon also contributes to the maintenance of potassium balance, but this adaptation cannot compensate fully for the decrease in renal potassium excretion that occurs with advanced kidney disease.

**METABOLIC ACIDOSIS**

Individuals with normal kidney function generate enough hydrogen ion to reclaim all filtered bicarbonate and to secrete approximately 1 mEq/kg per day (1 mmol/kg per day) of hydrogen ions, which are generated from the metabolism of dietary proteins (see Chap. 61). As a result, a constant body fluid pH is maintained through the buffering of hydrogen ion by proteins, hemoglobin, phosphate, and bicarbonate. Renal ammoniagenesis and phosphate excretion buffer the urine and facilitate acid excretion. In advanced CKD, all filtered bicarbonate is reclaimed, but the ability of the kidneys to synthesize ammonia is impaired. This decrease in urinary buffer results in decreased net acid excretion and continuous positive hydrogen ion balance; consequently, metabolic acidosis develops. Clinically significant metabolic acidosis is commonly seen when the GFR drops below 30 mL/min/1.73 m\(^2\) (0.29 mL/s/m\(^2\)) (stage 4 CKD) and the plasma bicarbonate concentration tends to stabilize at 15 to 20 mEq/L (15 to 20 mmol/L). Treatment is required to maintain the bicarbonate at the recommended target of 22 mEq/L (22 mmol/L) in this population.

**ANEMIA OF CHRONIC KIDNEY DISEASE**

The primary cause of anemia in CKD patients is a decrease in production of erythropoietin by the proximal tubular cells of the kidney, where approximately 90% of production occurs. Plasma concentrations of erythropoietin increase exponentially in response to decreased oxygenation in individuals with normal kidney function as hemoglobin and hematocrit decline. In contrast, there is no correlation between the degree of anemia and erythropoietin concentrations in anemic ESRD patients. The result is a normochromic (normal colored red cell), normocytic (normal size red cell) anemia. There is a strong correlation between the prevalence of anemia and the stage of CKD, with prevalence estimates of approximately 50% in stage 4 CKD and 75% for stage 5 CKD patients at the start of dialysis.

Iron demands increase when red blood cell production is stimulated by an erythropoietin stimulating agent (ESA) such as epoetin alfa; therefore, iron deficiency is common in individuals with CKD and is the leading cause of resistance to ESAs. Iron supplementation is often necessary to correct and prevent iron deficiency. Hepcidin is a hormone produced by the liver that is responsible for regulation of iron. This hormone directly inhibits the protein ferroportin that transports iron out of storage cells. When iron stores are high, hepcidin production is increased to block the transfer of iron from enterocytes to the plasma. Conversely hepcidin production is decreased when iron stores are low. Hepcidin production is also induced by inflammation or infection. As a result the increase in hepcidin in inflammatory conditions may lead to a sequestration of iron and ineffective red blood cell production (e.g., iron-restricted erythropoiesis). The fact that hepcidin plays such a role in iron regulation has prompted the development of hepcidin antagonists to potentially alter iron transport.

Additional factors contributing to the development of anemia of CKD are the decreased red cell life span (from the normal of 120 days to approximately 60 days in individuals with stage 5 CKD), vitamin B\(_12\) and folate deficiencies, and blood loss from regular laboratory testing and hemodialysis for patients requiring this modality of renal replacement therapy. A schematic of the process of red blood cell production is shown in Figure 53–1 that includes factors that impair this process in individuals with CKD.

Anemia in the CKD population has been associated with decreased quality of life, increased hospitalizations, and cardiovascular disease. ESAs have been shown to reduce these morbidities; however, there is now increasing evidence that treatment of anemia to hemoglobin targets above 12 g/dL (120 g/L; 7.45 mmol/L) may lead to increased risk of cardiovascular events and death. Thus treatment approaches have shifted to less aggressive use of ESAs and more conservative goals for Hb in the CKD population.

**CKD-MINERAL AND BONE DISORDER (CKD-MBD) AND RENAL OSTEODYSTROPHY**

Disorders of mineral and bone metabolism are common in the CKD population and include abnormalities in parathyroid hormone (PTH), calcium, phosphorus, the calcium-phosphorus product, vitamin D and bone turnover, as well as soft tissue calcifications. Historically these abnormalities have been described as classic characteristics of secondary hyperparathyroidism and renal osteodystrophy (ROD). Recently the term CKD-mineral and bone disorder (CKD-MBD) has been advocated to encompass the abnormalities in mineral and bone metabolism as well as associated calcifications.

The pathophysiology of CKD-MBD is complex (Fig. 53–2). Calcium and phosphorus homeostasis is mediated through the effects of four hormones on bone, the GI tract, kidney, and parathyroid gland. These hormones include PTH, the precursor
form of vitamin D known as 25-hydroxyvitamin D (25-OHD), active vitamin D or 1,25-dihydroxyvitamin D (calcitriol), and fibroblast growth factor-23 (FGF-23). As kidney function declines there is a decrease in phosphorus elimination, which results in hyperphosphatemia and a reciprocal decrease in serum calcium concentration. Hypocalcemia is the primary stimulus for secretion of PTH by the parathyroid glands. PTH secretion is suppressed by the interaction of ionized calcium with the calcium-sensing receptor on the chief cells of the parathyroid gland. Hyperphosphatemia also increases PTH synthesis and release through its direct effects on the parathyroid gland and production of prepro-PTH messenger RNA. In an attempt to normalize ionized calcium, PTH decreases

**FIGURE 53-2.** Pathogenesis of CKD-MBD and renal osteodystrophy. (*These adaptations are lost as kidney disease progresses.*)
phosphorus reabsorption and increases calcium reabsorption by the proximal tubules of the kidney (at least until the GFR falls to less than approximately 30 mL/min) and also increases calcium mobilization from bone. FGF-23 production in bone also increases and promotes phosphate excretion by the kidney. The result is a resetting of the calcium and phosphorus homeostasis set point, at least in the early stages of CKD; however, this occurs at the expense of an elevated PTH (“the trade-off hypothesis”). With advanced kidney disease the kidney fails to respond to PTH or to FGF-23. The increase in PTH is most notable when GFR is less than 60 mL/min/1.73 m² (stage 3 CKD) and worsens as kidney function further declines. Elevated PTH levels have been reported in approximately 21% of patients with an estimated GFR between 60 and 69 mL/min/1.73 m² (0.58 and 0.66 mL/s/m²) and in 56% of patients with stage 3, 4, or 5 CKD. The most active form of vitamin D (1,25-dihydroxyvitamin D, or calcitriol) promotes increased intestinal absorption of calcium, which helps to normalize ionized calcium. Calcitriol also works directly on the parathyroid gland to suppress PTH production. The enzyme 1α-hydroxylase is responsible for the final hydroxylation and conversion of the vitamin D precursor, 25-hydroxyvitamin D, to the active form in the kidney. As kidney disease progresses the process is impaired and the resultant vitamin D deficiency leads to reduced intestinal calcium absorption and worsening hyperparathyroidism. Increases in FGF-23, which facilitate excretion of phosphorus, may also promote calcitriol deficiency. Calcitriol deficiency is observed at all levels of GFR but is more prevalent in individuals with stage 3 CKD. Many individuals with CKD are also deficient in 25-OH vitamin D. This may be the result of decreased dermal synthesis of vitamin D, decreased exposure to sunlight, and reduced dietary intake of vitamin D. In patients with stage 3 or 4 CKD, 25-OH deficiency (levels of <30 ng/mL [<75 nmol/L]) are associated with increased PTH. Evaluation of 25-OH levels and supplementation with a vitamin D precursor (e.g., ergocalciferol or cholecalciferol) in patients with observed deficiencies are recommended for stages 3 and 4 CKD (opinion-based recommendation).

The abnormalities of CKD-MBD lead to bone abnormalities and other associated consequences. The continuous high rate of production of PTH by the parathyroid glands promotes parathyroid hyperplasia. Nodular tissue demonstrates more rapid growth potential and appears to be associated with fewer vitamin D and calcium-sensing receptors, resulting in resistance to the effects of calcium and vitamin D therapy and subsequent development of ROD. Bone abnormalities are found almost universally in ESRD patients and in the majority of those with stages 3–5 CKD. The skeletal complications associated with the bone abnormalities include osteitis fibrosa cystica (high bone turnover disease), osteomalacia (low bone turnover disease), and adynamic bone disease. Osteitis fibrosa cystica is most common and is characterized by areas of peritrabecular fibrosis. Bone marrow fibrosis and decreased erythropoiesis are also consequences of severe osteitis fibrosa cystica. Osteomalacia was historically noted in hemodialysis patients with aluminum toxicity, a finding less common today due to the decreased use of aluminum-containing phosphate binders and changes in the processing of dialysate solutions to decrease aluminum absorption. Adynamic lesions are characterized by low amounts of fibrosis or osteoid tissue and low bone formation rates. The incidence of adynamic lesions has increased over the last 10 years and may be present in as many as 50% of dialysis patients. Multiple risk factors for the development of this bone disease have been identified: high concentrations of dialysate calcium along with high doses of calcium-containing phosphate binders, aggressive management with vitamin D therapy, diabetes, aluminum toxicity, and advanced age. Symptoms of ROD are often not evident until after significant skeletal damage has developed; consequently, prevention is the key to minimize the consequences of long-term complications. When symptoms such as bone pain and skeletal fractures occur, the disease is not easily amenable to treatment.

Of concern with CKD-MBD is the increased mortality associated with this complication. Secondary hyperparathyroidism (SHPT) as evidenced by PTH levels >495 pg/mL (>495 ng/L) in CKD patients is associated with increased morbidity and mortality and sudden death in hemodialysis patients. Elevations of serum phosphorus, even within the upper limits of the normal range, have been associated with increased risk of cardiovascular events and/or mortality (all-cause or cardiovascular mortality) in patients with stages 3–5 CKD. An elevated calcium times phosphorus product (Ca × P) is also associated with poor outcomes, including vascular calcification, cardiovascular disease, calciphylaxis, and death. In two large, national, cross-sectional samples of hemodialysis patients who had received dialysis for at least 1 year, elevated serum phosphorus levels and Ca × P were associated with increased risk of death. Patients with a Ca × P above 72 mg/dL² (5.8 mmol/L²) were found to have a 34% higher risk of death compared with patients with a Ca × P in the desired range of 43 to 52 mg/dL² (3.5 to 4.2 mmol/L²). Calcium scores, as measured by electron-beam computed tomography, were significantly higher in hemodialysis patients than in patients without kidney disease who had proven coronary artery disease. Intake of calcium from calcium-based binders also appears to be a significant contributor to coronary artery calcification, even in young dialysis patients. The incidence of calciphylaxis in patients with ESRD has increased over the last decade and has also been linked to elevated Ca × P product, although a direct cause and effect relationship has not been established. These data underscore the need to consider all the consequences of elevated PTH, calcium, and phosphorus, not just their effects on bone.

CARDIOVASCULAR DISEASE

Patients with CKD are at increased risk of cardiovascular disease, independent of the etiology of their kidney disease. Mortality secondary to cardiovascular disease is 10 to 30 times greater in dialysis patients than in the general population. Higher mortality has also been observed in individuals with stages 3–5 CKD. In a study with data from over 1,120,295 individuals from a Kaiser Permanente Renal Registry higher mortality and risk of cardiovascular events were reported for individuals with stage 3–5 CKD compared to those with an estimated GFR above 60 mL/min/1.73 m² (0.58 mL/s/m²) (reference group). The rate of death from any cause was 17% greater for individuals with stage 3 CKD and 60% greater in those with stage 5 CKD not requiring dialysis. The rate of cardiovascular events was also greater compared with the reference group, with an increase of 43% observed for those with stage 3 CKD and 343% for individuals with stage 5 CKD. A cardiovascular event was defined as hospitalization for coronary heart disease, heart failure, ischemic stroke, and peripheral arterial disease.

Although a clearly unique pathogenesis of cardiovascular disease specific to CKD has not been identified, it is known that manifestations of kidney disease are contributory. Like diabetes CKD is considered a “coronary heart disease equivalent.” In addition to traditional cardiac risk factors such as hypertension and hyperlipidemia, diabetes, tobacco use, and physical inactivity, patients with kidney disease have other unique risk factors. Among these are hyperhomocysteinemia, elevated levels of C-reactive protein, increased oxidant stress, and hemodynamic overload. Complications of CKD such as anemia and metabolic disorders (i.e., CKD-MBD) are also contributory. In particular, arterial vascular disease (e.g., atherosclerosis) and cardiomyopathy are the primary types of cardiovascular disorders present in the CKD population. These disorders lead to development of ischemic heart disease and
its manifestations including myocardial infarction. As a predominant comorbidity, cardiovascular disorders and their sequelae are the leading cause of death in the ESRD population.\(^2\)^\(^3\)

**Hypertension**

The pathogenesis of hypertension in CKD is multifactorial, but for many, fluid retention is a major contributor. In addition to the other pathophysiologic mechanisms responsible for the development of hypertension, patients with ESRD may also have increased sympathetic activity, decreased activity of vasodilators such as nitric oxide, elevated levels of endothelin-1, chronic use of an ESA, hyperparathyroidism, and structural changes in the arteries (e.g., metastatic calcification) as contributing factors.\(^5\) Patients with ESRD also display an abnormal diurnal blood pressure rhythm as evidenced by the fact that their blood pressure does not decrease during the nighttime hours.\(^6\) It is unclear what causes this disturbance in the diurnal rhythm, but this “nondipping” phenomenon indicates sustained elevations in blood pressure are present over a prolonged period of time when compared with the general population.

Based on data from the 2009 USRDS, nine in ten Medicare CKD patients age 65 and older have a diagnosis of hypertension, an increase from 72% in 1995.\(^2\) Hypertension induced by volume expansion and increased systemic vascular resistance increases myocardial work and contributes to development of left ventricular hypertrophy (LVH). A “U-shaped” relationship between blood pressure and mortality has been observed, such that higher mortality is associated with the highest and lowest levels of blood pressure.\(^7\)

**Hyperlipidemia**

CKD with or without nephrotic syndrome is frequently accompanied by abnormalities in lipoprotein metabolism. It is well established that dyslipidemias cause atherosclerotic cardiovascular disease, and there are many compelling reasons to aggressively treat these disorders. A clear association between hypercholesterolemia, hypertriglyceridemia, or other lipoprotein changes in patients with CKD and cardiovascular disease has not been demonstrated in large prospective studies because individuals with kidney disease are usually excluded from these trials. It is likely that the same lipoprotein abnormalities that confer increased risk of cardiovascular disease in the general population would also be harmful to patients with kidney disease. This is supported by information from the Atherosclerosis Risk in Communities (ARIC) study.\(^8\) In this study, the association between the severity of dyslipidemia and risk of future cardiovascular events evaluated over a 10.5-year follow-up period was similar to that in patients who had normal kidney function.\(^9\)

A low or declining serum cholesterol in patients with ESRD is also associated with higher mortality, a paradoxical effect.\(^7\) These findings beg the question of whether aggressive lipid lowering is warranted in this population. Further analysis, however, shows that low cholesterol levels were observed in conjunction with inflammation and malnutrition, factors that increase mortality. In the absence of these confounding factors, it is the higher cholesterol levels, not the lower levels, that were associated with increased mortality.

The lipid panel generally observed in patients with CKD without nephrotic syndrome is a normal total and low-density lipoprotein (LDL) cholesterol, low high-density lipoprotein (HDL), and high triglycerides (plasma concentrations >200 mg/dL [>2.26 mmol/L]).\(^10\) Although the concentrations of LDL are not uniformly increased in patients with kidney disease, these patients appear to produce small, dense LDL particles that are more susceptible to oxidation and more atherogenic than larger LDL subfractions. Other lipoprotein abnormalities include changes in apoprotein content of lipoprotein molecules and increased very-low-density and intermediate-density lipoproteins. For patients with CKD and a urinary protein excretion greater than 3 g/day (as in nephrotic syndrome), the major lipid abnormalities are elevation of plasma total and LDL cholesterol, with or without low HDL cholesterol (<35 mg/dL [<0.91 mmol/L]) and elevated triglycerides. Treatment of proteinuria resolves the hyperlipidemia in most patients with nephrotic syndrome.

**CLINICAL PRESENTATION**

Damage to the kidney has detrimental consequences for many other organ systems, particularly once patients develop ESRD. The subjective and objective findings of CKD that may be present in an individual are dependent on the severity of disease (i.e., stage of CKD). At the time of referral to a nephrologist patients may present with some, but rarely all, of the signs and symptoms associated with uremia and secondary complications of CKD, unless they are in stage 4 or 5 CKD. It is apparent that management of CKD requires treatment of multiple secondary complications. Unfortunately many CKD patients are not diagnosed with the disease until they reach stage 5 CKD and are at or near the point of requiring renal replacement therapy. This problem has prompted automated reporting of the estimated glomerular filtration rate (eGFR) by clinical labs as determined by the MDRD equation for the purpose of identifying individuals with CKD earlier (see Chaps. 50 and 52). Clinicians must understand how to interpret the eGFR appropriately to stage individuals with kidney disease and determine the best options to delay progression and manage the associated complications.

**CLINICAL PRESENTATION OF STAGE 4 OR 5 CHRONIC KIDNEY DISEASE**

**Symptoms**

- Uremic symptoms (fatigue, weakness, shortness of breath, mental confusion, nausea and vomiting, bleeding, and loss of appetite), as well as itching, cold intolerance, weight gain, and peripheral neuropathies are common in patients with stage 5 disease.

**Signs**

- Edema, changes in urine output (volume and consistency), “foaming” of urine (indicative of proteinuria), and abdominal distension.

**Laboratory Tests**

- Decreased: creatinine clearance, bicarbonate (metabolic acidosis), hemoglobin/hematocrit (anemia), iron stores (iron deficiency), vitamin D levels, albumin (malnutrition), glucose (may result from decreased degradation of insulin with impaired kidney function or poor oral intake), calcium (in early stages of CKD), HDL.

- Increased: serum creatinine, blood urea nitrogen, potassium, phosphorus, PTH, blood pressure (hypertension is a common cause and result of CKD), glucose (uncontrolled diabetes is a cause of CKD), low-density lipoprotein and triglycerides, calcium (in ESRD)

- Other: May be hemocult-positive if GI bleeding occurs secondary to uremia.

**Other Diagnostic Tests**

- Left ventricular hypertrophy may be observed, as well as increased homocysteine levels and increased C-reactive protein.

### ANEMIA OF CHRONIC KIDNEY DISEASE

Since many individuals with anemia of CKD are asymptomatic upon presentation, laboratory evaluation is commonly the initial approach to diagnosing anemia of CKD. According to the KDOQI guidelines for anemia management in CKD the hemoglobin (Hb) should be measured in all individuals with CKD regardless of stage. The diagnosis of anemia is made and further workup of anemia is required when the Hb is less than 13.5 g/dL (135 g/L; 8.38 mmol/L) for adult males and less than 12 g/dL (120 g/L; 7.45 mmol/L) for adult females. Iron deficiency is the primary cause of resistance to treatment of anemia with ESAs; therefore, assessment of the iron status is required. The iron indices transferrin saturation (Tsat) and serum ferritin provide information on iron immediately available for use in the bone marrow for red blood cell production (Tsat) and storage iron (serum ferritin). The Tsat is calculated as ([serum iron / TIBC] × 100), where TIBC is the total iron-binding capacity. If the Tsat and serum ferritin values are below the desired threshold (Table 53–2), iron supplementation is warranted.

Additional workup includes evaluation for the presence of other potential causes of anemia such as blood loss, deficiencies in vitamin B₁₂, or folate, or other disease states that contribute to anemia, including human immunodeficiency virus infection and malignancies. Red blood cell indices (mean corpuscular hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin concentration), white blood cell count, differential and platelet count, and absolute reticulocyte count should also be assessed. A stool guaiac test should be performed to rule out GI bleeding.

Iron supplementation is required by most CKD patients receiving an ESA because of the increased iron demand that results from stimulation of red blood cell production. As CKD worsens, a progressive decline in Hb despite ESA therapy may be observed. Consequently, regular evaluation of Hb and iron status is warranted to ensure the desired outcomes are met and to make necessary dose adjustments in ESAs and iron therapy. Iron supplementation may also be required in individuals with anemia who have iron restricted erythropoiesis. In this condition the individual with anemia may have a Tsat below goal (less than 20% [0.20]); however, the serum ferritin may be at goal (e.g., above 100–200 ng/mL [100–200 μg/L]) or even elevated. It has been shown that anemic hemodialysis patients with a Tsat less than 25% (0.25) and serum ferritin between 200 and 1200 ng/mL (200–1200 μg/L) had an improved response to ESAs when they also received a 1 g course of IV iron. Signs and symptoms of anemia of CKD include, but are not limited to, fatigue, shortness of breath, cold intolerance, chest pain, tingling in the extremities, tachycardia, headaches, and general malaise. The effects of anemia and decreased oxygen delivery on other comorbid conditions, including LVH, have been considered given the burden of cardiovascular complications in this population. Despite associations of worsening anemia with development of LVH, there are no prospective studies demonstrating that early and aggressive treatment improves cardiovascular end points or LVH in the CKD population. Improvements in quality of life have been observed with increased Hb, but such improvements must be weighed against reported risks of more aggressive anemia management to achieve higher Hb levels in the CKD population.

### CKD-MINERAL AND BONE DISORDER (CKD-MBD) AND RENAL OSTEODYSTROPHY

The K/DQOII clinical practice guidelines for bone metabolism and disease have been available since 2003 and provide recommendations for the workup and treatment of CKD-MBD. In 2009 the KDOQI clinical practice guidelines for CKD-MBD were published. Recommendations from both the K/DQOII and KDOQI are presented here. It should be noted that many of the recommendations are based on opinion or limited evidence given the lack of randomized, controlled studies to evaluate outcomes of treating the biochemical abnormalities to specific targets.

The biochemical abnormalities of CKD-MBD should be evaluated in patients with stage 3 CKD and include an evaluation of serum phosphorus, calcium, Ca × P product, and PTH. The recommended frequencies of monitoring calcium, phosphorus, and PTH by CKD stage based on the K/DQOII and KDOQI guidelines are shown in Table 53–3. The KDOQI guidelines also recommend monitoring bone-specific alkaline phosphatase annually in stage 4 and 5 CKD patients. The frequency of monitoring these parameters may increase once a diagnosis of CKD-MBD is made and further information is needed to assess the patient’s response to treatment and to guide decisions about changes in therapy.

Clinicians involved in the care of patients with CKD should know which PTH assays are available in their facilities. PTH is secreted from the parathyroid gland as intact PTH, an 84-amino-acid peptide chain (1–84 PTH) that is biologically active, and as smaller carboxy-terminal PTH fragments. Circulating levels of these fragments (e.g., 7–84 PTH) may increase substantially in patients with CKD and actively antagonize the effects to 1–84 PTH. The available immunoradiometric assays, known as second-generation assays,

KDOQI, Kidney Disease: Improving Global Outcomes; K/DQOII, Kidney Disease Outcomes Quality Initiative; PTH, parathyroid hormone.
measured not only the intact PTH molecule but also fragments, which may lead to overestimation of biologically active PTH. A correction factor for these fragments cannot be established since commercially available assays measure different types and amounts of these fragments and give inconsistent results. For this reason KDIGO did not specify a particular PTH target, but rather advocated looking at trends in serum PTH to make treatment decisions. For the dialysis population KDIGO recommends a general PTH range of two to nine times the upper limit of the normal range for the assay. This differs from the K/DOQI guidelines which recommend specific ranges for each stage of CKD (Table 53–4). The risks associated with sustained elevations in PTH that would be permitted by following the KDIGO guidelines have raised concern and, at present, the K/DOQI recommendations continue to serve as the basis for treating CKD-MBD.

In addition to monitoring for biochemical abnormalities that define CKD-MBD and are associated with negative outcomes, evaluation of bone architecture is also necessary in some cases. Individuals with stages 3–5 CKD and metabolic abnormalities of CKD-MBD (e.g., abnormal phosphorus, calcium, PTH, and vitamin D) with bone involvement are said to have renal osteodystrophy. The gold standard test for diagnosing renal osteodystrophy is bone biopsy for histologic analysis; however, this is an invasive test that is not easily performed. Both K/DOQI and KDIGO guidelines recommend bone biopsy only in patients in whom the etiology of symptoms is not clear or in individuals with more unique biochemical abnormalities. This includes patients experiencing unexplained fractures, persistent hypercalcemia, and possible aluminum toxicity. If aluminum concentrations are elevated (60 to 200 μg/L [2.2 to 7.4 μmol/L]) a dexamethasone test should be done. KDIGO also suggests a bone biopsy be considered in CKD patients prior to beginning treatment with bisphosphonates since adynamic bone disease is a contraindication to the use of these agents. Bone biopsy findings are described on the basis of turnover rate, mineralization, and volume. High bone turnover disease, or osteitis fibrosa, is a common pattern observed with renal osteodystrophy, although individuals may also have low bone turnover disease. Bone mineral density testing is not generally recommended in patients with advanced CKD since this test has not been shown to predict fracture risk and does not indicate the type of renal osteodystrophy.

Abnormalities in mineral metabolism are highly associated with vascular and soft-tissue calcifications, known risk factors for mortality; therefore, diagnostic testing for calcifications should be considered in the evaluation for CKD-MBD. Electron-beam computed tomography (EBCT) is a noninvasive and sensitive method available for detecting cardiovascular calcifications and has been used clinically and in studies in the CKD population. Other methods advocated include lateral abdominal radiographs to detect vascular calcification and echocardiogram to detect cardiac calcification. KDIGO suggests these tests are reasonable alternatives to EBCT based on the sensitivity to detect calcifications and lower cost.

* Differences with Kidney Disease: Improving Global Outcomes (KDIGO) described in text (see CKD-MBD Desired Outcome section).

**METABOLIC ACIDOSIS**

Metabolic acidosis generally does not occur until stage 4 CKD. The complete evaluation of acid–base status requires measurement of serum electrolytes and arterial blood gases when acidosis is suspected. A complete medical history and review of medications is necessary to determine whether there are other potential causes of acid–base disturbances (e.g., diuretics, diabetics, ingestion of toxins, or GI disorders). The anion gap, indicating the differences in unmeasured cations and anions, should also be calculated (see Chap. 61). An elevated anion gap (>17 mEq/L > 17 mmol/L) is often present in patients with stage 4 or 5 CKD because of the accumulation of organic anions, phosphates, and sulfates. Treatment of metabolic acidosis in patients with CKD generally includes administration of bicarbonate to correct acidemia with the time course for correction depending on the severity of the acidosis. Asymptomatic patients with mild acidosis (bicarbonate of 12 to 20 mEq/L [12 to 20 mmol/L]; pH of 7.2 to 7.4) generally do not require emergency therapy, and gradual correction with oral bicarbonate administration over days to weeks is appropriate.

**CARDIOVASCULAR DISEASE**

Individuals with CKD are at increased risk for CVD; thus screening for the presence of cardiovascular risk factors is a high priority in this population. Individuals with stage 4 CKD should be assessed for cardiovascular risk factors and considered in the highest risk group for cardiovascular events. The risk of developing congestive heart failure increases in both young and elderly CKD patients. Modifiable cardiovascular risk factors in patients with CKD are hypertension, diabetes mellitus, hyperlipidemia, and smoking. The K/DOQI guidelines for stage 5 dialysis patients recommend that all patients starting dialysis be assessed for cardiovascular disease (including coronary artery disease, cardiomyopathy, valvular heart disease, cerebrovascular disease, and peripheral vascular disease) and be screened for traditional (e.g., hypertension and hyperlipidemia) and nontraditional cardiovascular risk factors.

**Hypertension**

As in the general population patients with CKD may not have symptoms of elevated blood pressure; therefore, blood pressure monitoring is essential. Edema and other indications of volume expansion may be observed in individuals with hypertension as a result of volume overload. Patients with stages 4 and 5 CKD should have their blood pressure evaluated at every clinic visit and at home, if feasible. Patients with ESRD should have their blood pressure monitored at every scheduled clinic visit (or hemodialysis session), and they should also be encouraged to learn how to monitor their blood pressure while at home. Patients who have required extensive surgeries in both arms to establish vascular accesses should have blood pressure measured in the thighs or legs. Blood pressure should be measured with an appropriate-size cuff prior to insertion of the needles for hemodialysis.
Blood pressure monitoring performed in the clinical setting has been shown to both overestimate and underestimate true blood pressure in CKD patients. Ambulatory blood pressure monitoring (ABPM) is recommended in individuals with CKD to better determine variations in blood pressure throughout the day and to detect the “nondipping phenomenon” (loss of the protective decline in blood pressure that occurs during sleep) that is more common in the CKD population. ABPM has also been shown to better correlate with end organ damage (e.g., proteinuria) than blood pressure readings measured in the clinical setting. ABPM is also recommended for dialysis patients since both pre- and postdialysis blood pressures are poor indicators of interdialytic blood pressure.

**Hyperlipidemia**

A complete fasting lipid profile including total cholesterol, LDL, HDL, and triglycerides should be done in all CKD patients. Lipoprotein levels may be influenced by several factors, including GFR and proteinuria. It is recommended that CKD patients have their lipid profile assessed more frequently than the general population to identify abnormalities and treat them early. In patients on hemodialysis the lipid profile should be done prior to dialysis or on nondialysis days. Patients should also be evaluated for other conditions that are known to cause dyslipidemias (e.g., liver disease).

**TREATMENT**

**Chronic Kidney Disease**

Once a patient is diagnosed with CKD, implementation of therapy to address the primary cause (e.g., diabetes, hypertension, or glomerulonephritis) and to delay progression is a priority. The key concepts involved in the management of disease progression are discussed in detail in Chapter 52. When patients reach stage 4 CKD, progression to ESRD is almost inevitable, although the process may be delayed if appropriate therapy is initiated. It is during stage 4 CKD that planning for renal replacement therapy (hemodialysis or peritoneal dialysis) should begin, including patient education about dialysis modalities and options for transplantation (see Chap. 54 and 98).

**Individuals with CKD should be evaluated for secondary complications (e.g., anemia and CKD-MBD) and comorbid conditions and receive treatment for these complications prior to development of ESRD. Historically, the common complications of anemia and CKD-MBD have not been diagnosed or appropriately managed in the earlier stages of CKD. Late referral to a nephrologist may in part account for this poor management; however, even in ideal clinical environments such as nephrology clinics, these secondary complications may be overlooked. There are opportunities for other healthcare professionals to make recommendations for appropriate workup and management of CKD and its associated complications.**

**GENERAL APPROACH TO PATIENT CARE**

Management of the existent complications and consequences of CKD should be based on the most current consensus guidelines and the best clinical practices such as those developed by the NKF-KDOQI, KDIGO, Cochrane Renal group, and other relevant professional associations. The K/DOQI guidelines and recommendations were developed based on evidence, when available, or the opinion of an expert group of individuals when sufficient evidence was lacking. Recommendations based primarily on opinion have been subject to some criticism. With this in mind, the K/DOQI guidelines should not replace clinical judgment, but should provide a basis upon which treatment decisions can be made in the context of both evidence and opinion. The secondary complications that are addressed in the currently available clinical practice guidelines include anemia of CKD, bone metabolism and disease, cardiovascular disease in dialysis patients, dyslipidemias, hypertension, and nutrition.

Appropriate management of secondary complications of CKD ideally involves a multidisciplinary approach to address the nonpharmacologic and pharmacologic interventions, dietary education, and social/financial concerns. The typical team includes physicians (nephrologists), nurses, dietitians, and social workers in outpatient dialysis facilities. In some outpatient dialysis centers pharmacists are also active members of the care team, although this is more common in dialysis units associated with healthcare institutions.

Reducing the incidence and risk of drug-related problems (DRPs) is one of the primary goals in caring for the CKD patient. ESRD patients are prescribed an average of 8 to 10 medications, which increases the potential of DRPs. This risk is further compounded by the fact that many patients see practitioners outside of the dialysis unit and receive prescriptions from these providers in addition to the medications they require during dialysis. Medication reconciliation is essential to reduce the risk of DRPs and requires that pharmacists and other practitioners consult with the dialysis facilities to get a complete medication history. Pharmacists in the community must be prepared to provide medication therapy management (MTM) for individuals with CKD since this population receives medications and care in the community settings. Frequent medication reviews are paramount to reduce DRPs and patient exposure of these patients to nephrotoxic agents (see Chap. 54). Drug-dosing guidelines based on the degree of kidney function should be followed, and a complete medication history of prescription and nonprescription medications, as well as herbal and nutritional supplements, should be obtained and routinely updated. Chronic use of nonsteroidal antiinflammatory drugs and cyclooxygenase-2 inhibitors should be avoided when possible. Patients should be instructed on all brand and generic names of these classes of medications to reduce the risk of exposure. Appropriate measures should also be taken for hospitalized patients to decrease the risk of nephotoxicity from radiocontrast agents (for procedures requiring such dyes), and antibiotics such as aminoglycosides, as well as from nonsteroidal antiinflammatory drugs and angiotensin-converting enzyme inhibitors (ACEIs) (see Chaps. 51 and 55).

Continued patient education, initiated prior to development of ESRD, is essential to help patients become active participants in their own care and to become knowledgeable about medications which they often require on a chronic basis. Pharmacists involved with the dialysis population have identified many specific drug-related problems (e.g., inappropriate dose or indication for a medication, adverse drug reactions) that commonly occur in the ESRD population and have demonstrated that clinical pharmacy services reduce such problems and improve patient quality of life.

**DESIRED OUTCOME**

The overall goal of therapy in individuals with stage 2, 3, and the early phase of stage 4 CKD is to delay or prevent progression of the disease and the associated comorbidities. Patients who reach CKD stage 4 almost inevitably experience progression to ESRD and thus at some time in the near future will require dialysis or transplantation to sustain life. The primary goal is to sustain a good quality of life and prevent adverse outcomes by aggressively managing complications of advanced CKD.
FLUID AND ELECTROLYTE ABNORMALITIES

Maintenance of fluid volume, osmolarity, electrolyte balance, and acid–base status are all regulated in large part by the kidney and their homeostasis is altered in patients with impaired kidney function. A comprehensive discussion of fluid and electrolyte disorders and treatment options is presented in Chapters 58–60. The unique aspects of treatment of sodium, water, and potassium disorders in stage 4 CKD and dialysis patients are highlighted here.

Desired Outcomes

**Sodium and Water Homeostasis** The goal in the individual with CKD is to maintain sodium and water balance as indicated by serum sodium concentrations in the normal range (i.e., 135 to 145 mEq/L [135 to 145 mmol/L]) and a euclidean state. By achieving these goals, the risk of developing or worsening hypertension secondary to volume overload is reduced. Achievement of these goals is also warranted to prevent complications in individuals with congestive heart failure or other conditions that may be affected by volume status.

**Potassium Homeostasis** The focus is on prevention of hyperkalemia and its acute adverse consequences, particularly cardiac effects, while maintaining potassium concentrations of approximately 4 to 5.5 mEq/L (4 to 5.5 mmol/L). This is often achieved through dietary restriction of potassium, minimizing exposure to medications that may increase serum potassium, and use of sodium–potassium exchange resins when indicated. If hyperkalemia develops, management options are based on the rapidity and degree to which potassium is elevated (see Chap. 60).

Nonpharmacologic Therapy

**Sodium and Water Homeostasis** The ability of the kidney to adjust to abrupt changes in sodium intake is greatly diminished in patients with severe CKD. Sodium restriction beyond a no-added-salt diet should generally not be recommended. The kidney maintains the ability to lower urinary sodium content to essentially zero, but this can only be accomplished by very gradual sodium restriction over a period of several days. Hospitalized patients with CKD should not routinely be sodium restricted because they have adapted to their outpatient intake. Negative sodium balance and its resultant volume contraction can cause decreased kidney perfusion and an acute decline in GFR.

Fluid restriction is generally unnecessary for CKD patients not requiring dialysis provided sodium intake is controlled. An intact thirst mechanism maintains total-body water and effective plasma osmolality near normal. Large amounts of free water administered orally or as IV fluid may induce hyponatremia and volume overload. Sodium retention and volume expansion also contribute to hypertension in many patients with severe CKD, and diuretic therapy may be necessary to control edema or blood pressure. Saline-containing IV solutions should also be used cautiously in patients with CKD because the kidney’s ability to excrete a salt load is impaired and the kidneys are prone to volume overload. Sodium restriction (e.g., less than 2 g per day) is warranted in the ESRD population to help control volume status.

**Potassium Homeostasis** Hyperkalemia is more common in patients with stage 5 CKD and in those who require dialysis. The majority of patients can be managed with a dietary potassium restriction of 50 to 80 mEq/day (50 to 80 mmol/day) and a reduction in dialysate potassium concentrations (see Chap. 54). Hyperkalemia is less common in the peritoneal dialysis population because of the more extensive removal of potassium by the peritoneal dialysis procedure and therefore, these patients are often allowed more liberal dietary potassium intake.

**Pharmacologic Therapy**

**Sodium and Water Homeostasis** Diuretic therapy is often necessary to prevent edema and the associated symptoms from volume overload. Loop diuretics increase urine volume and renal sodium excretion even in individuals with stage 4 CKD. Diuretic resistance can occur and requires use of higher doses of loop diuretics. In these situations a combination of a loop diuretic with the thiazide diuretic, metolazone, can substantially increase excretion of sodium and water (see Chap. 58). When a patient develops ESRD diuretics become ineffective as residual kidney function is lost and dialysis becomes necessary to control volume status.

**Potassium Homeostasis** The definitive treatment of severe hyperkalemia for a dialysis-dependent ESRD patient is hemo-dialysis. In reality, there is often a delay between diagnosis of hyperkalemia and institution of dialysis, which necessitates the use of other temporizing measures, such as IV calcium gluconate, insulin and glucose, nebulized β-blockers (albuterol), and sodium polystyrene sulfonate (see Chap. 60). Unfortunately, shifting potassium into the intracellular fluid compartment with insulin and glucose or with albuterol makes removal of potassium via dialysis more difficult. Multiple dialysis sessions may be necessary following potassium redistribution to the extracellular space. Sodium polystyrene sulfonate, a potassium–sodium exchange resin, can be given orally in doses of 30 to 60 g to increase potassium excretion via the ileum and colon. Sodium bicarbonate therapy is no longer advocated in the treatment of ESRD hyperkalemia unless severe metabolic acidosis is also present because the potassium-lowering effect is unreliable. Loop diuretics, a standard pharmacologic treatment option for hyperkalemia, are ineffective in patients with ESRD.

Each patient’s medications should routinely be reviewed to identify those that increase serum potassium. This includes potassium-sparing diuretics, β-blockers, which interfere with the extrarenal translocation of potassium into cells, and ACEIs, which may cause hyperkalemia by reducing aldosterone production. Polycitra, used for the treatment of metabolic acidosis, contains potassium citrate and should not be prescribed for patients with severe CKD. The contribution of dialysis modalities to potassium homeostasis in patients with ESRD must also be considered (see Chap. 54). Constipation in patients with CKD can interfere with colonic potassium excretion; therefore a good bowel regimen is also important.

Evaluation of Therapeutic Outcomes

Monitoring of volume status and serum electrolyte levels should be done at each clinic visit in patients with stages 4 and 5 CKD. This should include an evaluation of signs and symptoms of extracellular fluid volume expansion (e.g., pitting edema, rales, ascites, shortness of breath, and increased weight) and consequences of volume overload (e.g., hypertension, pulmonary edema) and hyperkalemia (e.g., arrhythmias). Blood pressure monitoring in the clinic setting and at home, if feasible, is recommended to detect onset or worsening of hypertension and to monitor the efficacy of the antihypertensive regimens. As kidney disease progresses dietary intervention and diuretic therapy will likely become necessary.

Serum electrolytes are generally measured monthly in the dialysis population. Additional monitoring in the hemodialysis population includes assessment of the predialysis weight compared to a patient’s dry weight (the target weight following hemodialysis at which the patient is hemodynamically stable). The greater the difference in weight, the more volume an individual has accumulated since the last hemodialysis session. While the hemodialysis prescription can be altered acutely to remove more volume by
increasing ultrafiltration (see Chap. 54), a patient consistently gaining excessive weight between dialysis sessions will require counseling on restriction of sodium and water.

**ANEMIA OF CHRONIC KIDNEY DISEASE**

**Desired Outcome**

The desired outcomes of anemia management are to increase oxygen-carrying capacity, decrease signs and symptoms of anemia, improve the patient’s quality of life, and decrease the need for blood transfusions. Achievement of these goals requires a combination of an ESA and iron supplementation to promote and maintain erythropoiesis. Hemoglobin (Hb) is the preferred monitoring parameter for red blood cell production because, unlike Hct, its concentration is not affected by blood storage conditions and instrumentation used for analysis. Table 53–2 lists the target Hb and iron indices for those stage 5 CKD patients who are dialysis dependent as well as those not yet receiving dialysis.

**TABLE 53–2 Trials Evaluating ESAs and Target Hb/Hct**
16 g/dL (120–160 g/L; 7.45–9.93 mmol/L). There was also a higher risk of dialysis access thrombosis and uncontrolled blood pressure in the higher Hb group. Following the release of CHOIR and CREATE the Centers for Medicare and Medicaid Services (CMS), which pays dialysis facilities for a significant portion of services, changed the reimbursement structure for ESAs to reduce payment by 50% if the Hb remained above 13 g/dL (130 g/L; 8.07 mmol/L) for 3 months or greater to promote more conservative and less costly use of ESAs.

The association of poor outcomes with dose of ESA used in the aforementioned studies has also raised concern. Subsequent analysis of the CHOIR study showed that high-dose ESA use was associated with greater risk of death. Those individuals able to achieve the target Hb in the CHOIR study did not have worse outcomes. Further analysis of the NHCT data also showed a reduction in mortality by 60% for those individuals who responded to epoetin therapy compared with nonresponders. Higher mortality with higher ESA dose has also been reported in other observational studies. Such findings have led to discussion of whether hyporesponsiveness to ESAs due to other conditions such as inflammation may explain the higher event rates in this group of individuals. The overall negative cardiovascular outcomes observed with higher Hb targets in the randomized trials has prompted much discussion about the potential causes, including not only ESA dose and Hb target but also the rate of rise in Hb and the variability in Hb over time (e.g., degree of fluctuation in Hb).

Additional discussion on this topic has also been stimulated by the initial results from the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT), a trial initiated prior to the release of data from the CHOIR and CREATE studies (Table 53–5). Despite the association between anemia and reduction in hospitalization and cardiovascular events that prompted many to expect positive outcomes from this study, individuals treated to the higher Hb target did not have a reduction in the defined primary end points compared with the lower Hb group. In addition, there was also an almost twofold increase in the risk of stroke (5% in the treatment group vs 2.6% in the placebo group). Those patients with a history of cancer in the higher Hb group also had a higher risk of death, a finding that requires additional investigation. These findings further support the recommendation of adhering to the recommendations in the labeling of not exceeding a Hb of 12 g/dL (120 g/L; 7.45 mmol/L).

**Nonpharmacologic Therapy**

Nonpharmacologic therapy for anemia of CKD includes maintaining adequate dietary intake of iron as well folate and B12. Patients on hemodialysis or peritoneal dialysis should be routinely supplemented with water-soluble vitamins (including B12 and folate) as these vitamins are often depleted with dialysis therapy. A relatively small amount of dietary iron, approximately 1 to 2 mg (or approximately 10%), is absorbed each day, primarily in the duodenum. Although there is some debate as to whether GI absorption of iron is significantly altered in patients with severe CKD, it is clear that oral intake from dietary sources alone is insufficient to meet the increased iron requirements from initiation of ESA therapy.

**Pharmacologic Therapy**

Pharmacologic therapy for anemia of CKD is based upon a foundation of ESA therapy to correct erythropoietin deficiency and iron supplementation to correct and prevent iron deficiency caused by ongoing blood loss and increased iron demands associated with the initiation of erythropoietic therapy (Figs. 53–3 and 53–4). Iron therapy is first-line therapy for anemia of CKD if iron deficiency is diagnosed, and for some patients the target Hb may be achieved without concomitant ESA therapy. For most individuals with advanced CKD, however, combined therapy with iron and an ESA is often required to effectively stimulate erythropoiesis.

**Iron Supplementation**

Options for iron supplementation include oral and IV therapy (Tables 53–6 and 53–7). Oral iron preparations differ in their content of elemental iron: ferrous salts (ferrous sulfate, ferrous fumarate, and ferrous gluconate), polysaccharide iron complex, and a heme iron polypeptide formulation. Five IV iron products are currently available in the United States (see Table 53–7): two composed of iron dextran (INFeD, molecular weight [MW] 96 kDa; and Dexferrum, MW 265 kDa), sodium ferric gluconate (Ferrlecit, MW 350 kDa), iron sucrose (Venofer, MW 43 kDa), and ferumoxytol (Feraheme, MW 750 kDa).

**Pharmacology and Mechanism of Action.** Iron supplements provide the elemental iron required for production of hemoglobin and its subsequent incorporation in red blood cells,
the net result of which is an increase in the transportation of oxygen to tissues.

**Bioavailability.** Approximately 10% of orally administered iron is absorbed in the duodenum and upper jejunum. Absorption of iron is decreased by food and achlorhydria. The heme form of oral iron binds to a different receptor in the GI tract than nonheme iron, is absorbed to a greater extent, and may be better tolerated. Some oral iron formulations also include ascorbic acid to enhance iron absorption.

Intravenous iron preparations are colloids that consist of an iron-containing core that is surrounded by a carbohydrate shell to stabilize the iron complex. Available agents differ in the size of the core and the composition of the surrounding carbohydrate. These differences affect the rate of dissociation of iron from the complex to phagocytes within the reticuloendothelial system where iron is either stored or released to the extracellular carrier protein transferrin, which transports iron to the bone marrow for red blood cell production. The half-lives of the available IV iron formulations differ: ferric gluconate (1 hour), iron sucrose (6 hours), ferumoxytrol (15 hours), and iron dextran (40 to 60 hours).

**Efficacy, Dosage, and Administration.** Although supplementation using oral preparations may seem more practical than IV administration, oral iron therapy is limited by poor absorption and nonadherence with therapy primarily due to adverse effects and,
thus, it is a challenge to achieve goal iron indices. If oral therapy is initiated, the recommended dose is 200 mg of elemental iron per day (see Table 53–6). Either oral or IV administration of iron is recommended in early-stage CKD and the peritoneal dialysis population. Oral iron supplementation is more convenient for these patients, who do not have regular IV access; however, at some point they are likely to require IV iron supplementation to meet iron needs and correct absolute iron deficiency, especially if receiving an ESA.

In patients with ESRD, GI absorption of iron is often inadequate to meet the increase in iron demand from ESA therapy and chronic blood loss in the hemodialysis population. K/DOQI guidelines recommend IV iron as the preferred route of administration in the hemodialysis population. Parenteral iron improves the responsiveness to ESA therapy and reduces the dose required to achieve and maintain the target Hb in hemodialysis patients. For the hemodialysis population typical repletion dosing regimens are 100 mg as iron sucrose or iron dextran over 10 dialysis sessions, or 125 mg of sodium ferric gluconate over 8 dialysis sessions (see Table 53–7). Ferumoxytol is administered as 510 mg at a rate not to exceed 30 mg per second (1 mL per second) with a second dose given within 3 to 8 days. Administration of 1 g of IV iron is recommended to initially replete hemodialysis patients with an absolute iron deficiency; however, without ongoing iron supplementation, many patients quickly become iron deficient. To prevent iron deficiency maintenance doses of IV iron are administered in hemodialysis patients (e.g., iron sucrose or iron dextran 25 to 100 mg/wk; sodium ferric gluconate 62.5 to 125 mg/wk) based on evidence of improved Hb and lower ESA doses with these regimens. 

\(^{a}\) Note that the goal Hb is 10–12 g/dL (100–120 g/L; 6.1–7.45 mmol/L) based on FDA labeling for ESAs

\(^{b}\) Do not adjust ESA dose more frequently than every 4 weeks as a general rule

**FIGURE 53-4.** Algorithm for erythropoietic stimulating agent therapy in the management of the anemia of CKD. (ESA, erythropoietic-stimulating agent; Hb, hemoglobin; SC, subcutaneous; TSat, transferrin saturation.)
Iron administration in patients with what is known as iron restricted erythropoiesis (also referred to as functional iron deficiency) is more questionable. Under these conditions a trial of IV iron therapy may be warranted if the Hb is less than the target of 11 g/dL (110 g/L; 6.83 mmol/L). A recent study conducted in ESA-treated anemic hemodialysis patients with a low TSat (<25% [<0.25]) and an elevated serum ferritin (>500 ng/mL; >500 μg/L) showed a significantly greater Hb response rate in patients who received a 1 g course of IV iron as sodium ferric gluconate in conjunction with a 25% increase in ESA dose than in those who only received an increase in the ESA dose.36

**Adverse Effects.** Adverse effects of oral iron are primarily GI in nature and include constipation, nausea, and abdominal cramping. These adverse effects are more likely as the dose is escalated and may be present in more than 50% of patients receiving 200 mg of elemental iron per day. These unfavorable effects often discourage patients from taking these medications on a chronic basis. Some of these GI side effects can be minimized if oral iron products are taken with food; however, food decreases absorption of oral iron. Patients should initially be instructed to take oral iron on an empty stomach; however, if side effects lead to intolerance and nonadherence these agents can be administered with food, or an alternative agent may be prescribed.

Adverse effects of IV iron include allergic reactions, hypotension, dizziness, dyspnea, headaches, lower back pain, arthralgia, syncope, and arthritis. Some of these reactions, in particular hypotension, can be minimized by decreasing the dose or rate of infusion of iron. The most concerning potential consequence of IV iron administration is anaphylaxis. Anaphylactoid reactions to iron dextran have been reported in up to 1.8% of patients, with serious reactions including respiratory complications and cardiovascular collapse occurring in approximately 0.6%.40 Such reactions are believed to be partly a response to antibody formation to the dextran component. Adverse reactions have been reported two to eight times more frequently in those receiving Dexferrum compared with INFeD.41 Based on the labeling for all iron dextran products clinicians should (a) administer a test dose of 25 mg prior to the first therapeutic dose; if there are no signs or symptoms of an anaphylactic-type reaction then administer the full therapeutic dose; (b) observe for signs or symptoms of anaphylactic-type reactions during and after every administration; and (c) note that patients with a history of drug
